APPENDIX

REVISITING GAIN OF FUNCTION RESEARCH: WHAT THE PANDEMIC TAUGHT US AND WHERE DO WE GO FROM HERE

WEDNESDAY, AUGUST 3, 2022

U.S. SENATE,
SUBCOMMITTEE ON EMERGING THREATS AND
SPENDING OVERSIGHT,
OF THE COMMITTEE ON HOMELAND SECURITY
AND GOVERNMENTAL AFFAIRS,
Washington, DC.

The Subcommittee met, pursuant to notice, at 2:30 p.m., via Webex and in room 342, Dirksen Senate Office Building, Hon. Rand Paul, presiding.

Present: Senators Ossoff, Paul, Scott, Hawley, and Johnson.

Also present: Senator Marshall.

OPENING STATEMENT OF SENATOR PAUL[1]

Senator PAUL. I call this meeting of the Senate Homeland Security and Governmental Affairs Subcommittee on Emerging Threats and Spending Oversight (ETSO) to order. I want to thank Senator Hassan for allowing this hearing to occur.

Welcome to each of our panelists. Thank you for joining us.

The purpose of this hearing by the Subcommittee on Emerging Threats and Spending Oversight is to discuss, as our name implies, the emerging threat posed by gain-of-function research. We will hear from a panel of three witnesses, all of whom are extraordinarily accomplished experts in the scientific community. We are grateful for their work and we are grateful to each of you for taking the time to appear with us this afternoon.

Gain-of-function (GOF) research is a controversial scientific research method involving the manipulation of pathogens to give them a new aspect or ability, such as making viruses more transmissible or dangerous to humans. Despite all we have learned about the potential risks of this particular method of research, this is the first congressional hearing on this subject since the pandemic began.

Today we will discuss what gain-of-function research entails, how gain-of-function research is defined, and whether the definition of gain-of-function research is applied consistently by the Department of Health and Human Services (HHS) Potential Pandemic Pathogens (P3CO) Review Committee. This is a committee that was set up to study potential pandemic pathogens.

[1] The prepared statement of Senator Paul appears in the Appendix on page 35.

We will discuss the responsibility for how we determine the risks and benefits. We will also discuss how this committee operates, how this committee approves or denies projects from receiving Federal funding based on whether the pathogen is considered to be a credible source of potential future human pandemic, and if the potential risks, as compared to the potential benefits to society, are justified. In other words, a project is not gain-of-function if the review committee is unsure if a recombinant virus will create a future pandemic.

There is a question of whether or not there is a reasonable expectation that it might be or whether or not it has been in the past, or what viruses should be and should not be experimented upon. This broad criterion gives one sole committee, which is comprised of an unknown group of bureaucrats—I believe the names are not released of who is on the committee so there is not necessarily any oversight of the oversight—the power to spend millions of taxpayer dollars on a single, preemptive guess, with potentially devastating consequences.

Today we will also consider whether gain-of-function research was performed at the Wuhan Institute of Virology (WIV). First, no one, not myself or anyone I am aware of, argues that a recombinant super-virus that has been published in scientific journals is Coronavirus Disease 2019 (COVID–19) or a close relative. If—and I underline "if"—COVID–19 leaked from the Wuhan lab, it would be a laboratory-created virus that the Wuhan scientists have not yet, and are unlikely ever to reveal.

I maintain that the techniques that the National Institutes of Health (NIH) funded in Wuhan to create enhanced pathogens may have or could have been used to create COVID–19. The American people deserve to know how this pandemic started and to know if the NIH funded research that may have caused this pandemic.

Gain-of-function research has the potential to unleash a global pandemic that threatens the lives of millions. Yet this is the first time the issue has been discussed in a congressional committee.

I am sure each Member of this Committee, as well as the full Senate, can agree that we need stronger government oversight of how our tax dollars are being used to finance experimenting with possibly fatal diseases.

Again, I thank each of our distinguished witnesses for being here today and I thank Chair Hassan for working with me to convene this meeting.

Before we begin I would like to note that I have invited Senators who are not on the Subcommittee to also attend today. Therefore, I ask unanimous consent (UC) to allow Senator Marshall and Senator Johnson to fully participate in the hearing, provided that any Members of the Subcommittee be given deference in the order of recognition. Without objection.

Next I would like to remind witnesses that any written testimony they have, anything that they have submitted, will be included in the record, and to please keep your opening remarks to around 7 minutes.

With that I am going to introduce the witnesses, and we will hear their remarks after the introduction, which is slightly dif-

ferent than we do sometimes, and then I will introduce the next witnesses.

The first witness will be with via WebEx. It is Dr. Richard Ebright. Dr. Richard Ebright is the Board of Governors Professor of Chemistry and Chemical Biology and the Director of the Waksman Institute of Microbiology at Rutgers University. Dr. Ebright completed his undergraduate degree from Harvard University in biology, where he earned summa cum laude honors. He later received a PhD in microbiology and molecular genetics, also from Harvard.

Dr. Ebright's research has led to over 175 publications as well as over 40 issued and pending patents. He has received numerous awards for research and is currently a member of the American Academy of Arts and Sciences as well as the Institutional Biosafety Committee at Rutgers University. He is a Fellow of the Infectious Disease Society of America, the American Academy of Microbiology, American Association for Advancement of Science. He was the editor of Molecular Biology for 16 years.

Dr. Ebright currently serves as the project leader of three current NIH research grants, has provided testimony to the House Committee on Energy and Commerce on the 2014 anthrax incident, and was a founding member of the Cambridge Working Group, whose cautionary statement on gain-of-function research involving potential pandemic pathogens remains as relevant as the day it was released in July 2014.

Dr. Ebright.

TESTIMONY OF RICHARD H. EBRIGHT, PH.D.,[1] LABORATORY DIRECTOR, WAKSMAN INSTITUTE OF MICROBIOLOGY, RUTGERS UNIVERSITY

Mr. EBRIGHT. Thank you. Chair Hassan and Members of the Committee, thank you for inviting me to discuss gain-of-function research and its oversight. I am Board of Governors Professor of Chemistry and Chemical Biology at Rutgers, the State University of New Jersey, and Laboratory Director at the Waksman Institute of Microbiology. In my oral statement I will discuss the definition of gain-of-function research of concern, risks and benefits of the research, U.S. oversight of the research, and steps to strengthen U.S. oversight of the research.

What is gain-of-function research of concern? Gain-of-function research of concern is defined as research activities reasonably anticipated to increase a potential pandemic pathogen's transmissibility, pathogenicity, ability to overcome immune response, or ability to overcome a vaccine or drug.

Gain-of-function research of concern involves the creation of new health threats, health threats that did not exist previously and that might not come to exist by natural means for tens, hundreds, or thousands of years.

Gain-of-function research of concern is a small part of biomedical research. It constitutes less than one-tenth of 1 percent of biomedical research and less than 1 percent of virology. However, because gain-of-function research of concern can cause pandemics,

[1] The prepared statement of Dr. Ebright appears in the Appendix on page 38.

this small part is highly consequential and requires effective oversight.

What are the risks? Gain-of-function research of concern poses high, potentially existential, risks. Gain-of-function research of concern poses material risks by creating new potential pandemic pathogens. If a resulting new potential pandemic pathogen is released into humans, either by accident or deliberately, this can cause a pandemic.

Gain-of-function research of concern also poses information risks, by providing information on the construction and properties of new potential pandemic pathogens. Publication of the research provides instructions, step-by-step recipes that can enable a rogue nation, organization, or individual to construct a new pathogen and cause a pandemic.

What are the benefits? Gain-of-function research of concern provides limited benefits. Gain-of-function research of concern can advance scientific understanding, but gain-of-function research of concern has no civilian practical applications. In particular, gain-of-function research of concern is not needed for, and does not contribute to, the development of vaccines and drugs. Companies develop vaccines and drugs against pathogens that exist and circulate in humans, not against pathogens that do not yet exist and do not circulate in humans.

What should oversight entail? Because gain-of-function research of concern poses high, potentially existential risks and provides limited benefits, the risk-benefit ratio for the research almost always is unfavorable and in many cases is extremely unfavorable. Therefore, it is imperative that gain-of-function research of concern be subject to national or international level oversight to ensure before the research is started that risk-benefit ratios are acceptable and risks are mitigated.

Effective oversight includes three components. First, research proposals that include gain-of-function research of concern must be identified and flagged. Second, a risk-benefit assessment must be performed. This entails enumerating risks and benefits, weighing risks and benefits, and reaching a decision, either to proceed as proposed or to proceed with additional risk mitigation, or not to proceed.

Third, compliance with the decision from the risk-benefit assessment must be mandated, monitored, and enforced.

I turn now to U.S. oversight of gain-of-function research of concern.

Before 2014, there was no national-level U.S. oversight of gain-of-function research of concern. In 2014 to 2017, the government put in place a moratorium on Federal funding for "selected gain-of-function research," defined as research activities reasonably anticipated to increase the transmissibility or pathogenicity of influenza, severe acute respiratory syndrome (SARS), or Middle East respiratory syndrome (MERS) viruses. The policy was referred to as the Pause.

Under the Pause, 18 projects were paused. However, at least 7 of the 18 projects that were paused were allowed to resume almost immediately. More important, other projects that met the definition for coverage, including a project on SARS-related coronaviruses by

EcoHealth Alliance and its Wuhan-based partners, were not paused, due to the failure of the NIH to identify and flag all covered projects.

At the end of 2017, the Pause was lifted and was replaced by an HHS policy that requires risk-benefit assessment before awarding HHS funding for "research involving enhanced potential pandemic pathogens," defined as research activities reasonably anticipated to increase the transmissibility or pathogenicity of a potential pandemic pathogen. The policy is referred to as the P3CO Framework.

Under the P3CO Framework, covered projects must be identified and flagged by the funding agency, the NIH, and covered projects must be reviewed by an HHS Secretary-level committee, the P3CO Committee.

The P3CO Framework assesses the reasonably anticipated results of the proposed research. The reasonably anticipated standard employed by the policy is equivalent, in all respects, to the reasonable person standard employed in U.S. administrative law and U.S. civil law.

In principle the P3CO Framework ensures risk-benefit assessment of gain-of-function research of concern. However, in practice, the P3CO Framework has existed primarily on paper. In the 4½ years since the policy was announced, only three projects have been reviewed. Most covered projects, including the project by EcoHealth Alliance and its Wuhan partners, were not reviewed, due to a failure by the NIH to identify and flag covered projects.

In addition, the P3CO Committee has been non-transparent and unaccountable. The names and agency affiliations of its members have not been disclosed, its proceedings have not been disclosed, and even its decisions have not been disclosed.

Current U.S. oversight of gain-of-function research of concern thus has serious shortcomings. Moving forward, any effective system of U.S. oversight of gain-of-function research of concern must address these shortcomings. My recommendations are as follows:

First, responsibility for U.S. oversight of gain-of-function research of concern should be assigned to a single, independent Federal agency that does not perform research and does not fund research.

Second, U.S. oversight of gain-of-function research of concern should cover all U.S. and U.S.-funded research, irrespective of funding source, classification status, and research location.

Third, U.S. oversight of gain-of-function research of concern should be codified in regulations with force of law and should be mandated, monitored, and enforced.

Fourth, U.S. oversight of gain-of-function research of concern should be transparent and accountable.

Thank you for your attention, and I would be pleased to address questions.

Senator PAUL. Thank you, Dr. Ebright.

Next we will have Dr. Steven Quay. Dr. Steven Quay is the Founder and Chairman of the Seattle-Based Atossa Therapeutics. Atossa Therapeutics is a clinical-stage biopharmaceutical company that develops novel therapeutics and delivery methods for breast cancer and other breast conditions, with the goal of preventing the two million yearly breast cancer cases worldwide.

Earlier in his career, Dr. Quay received his MD and PhD from the University of Michigan, trained as a postdoctoral fellow at Massachusetts Institute of Technology (MIT), and served on the faculty of Stanford University's School of Medicine.

Dr. Quay's published contributions to the world of medicine have been cited extensively, and he is a medical entrepreneur. He has founded six startups, invented seven Food and Drug Administration (FDA)-approved pharmaceuticals, and is the holder of 87 patents and over 130 pending U.S. and foreign patent applications.

He is also an author. Notably, during the pandemic, Dr. Quay published his No. 1 Amazon best seller, Stay Safe: A Physician's Guide to Survive Coronavirus.

Finally, Dr. Quay recently presented testimony to lawmakers as part of an expert forum convened by the House Select Committee on Coronavirus, titled "Led by Science: The COVID–19 Origin Story."

Dr. Quay.

TESTIMONY OF STEVEN QUAY, MD, PH.D.,[1] CHIEF EXECUTIVE OFFICER, ATOSSA THERAPEUTICS, INC.

Dr. QUAY. I am honored to participate with my esteemed colleagues, Doctors Ebright and Esvelt, in this forum entitled "Revisiting Gain-of-Function Research: What the Pandemic Taught Us and Where Do We Go From Here."

I offer six statements in opening. One, there is no dispositive evidence the pandemic began as a spillover of a natural virus in a market. All evidence is consistent with a laboratory-acquired infection. I do understand this conclusion is not widely held, I can spend an entire hearing painstakingly going through the scientific evidence for this conclusion, but that is not the purpose of today's meeting.

I am happy to discuss the evidence contained in my written remarks during questioning. I am also willing to publicly debate any virologist on this question, at any time or place. Only one infectious disease doctor was willing to debate this question with me last year in a formal debate format, and he lost.

I am also willing to testify under oath, if requested.

No. 2, all evidence is consistent with an accidental and not a deliberate release.

No. 3, SARS2 has features consistent with synthetic biology gain-of-function research. Two features involve acceptable academic gain-of-function research, the receptor binding domain optimization and the furin cleavage site. These two features have never been found in nature and related viruses that could have reasonably started the pandemic because of the closeness of these viruses to Wuhan.

These two features are, on the other hand, routinely engineered into viruses. In 2018, United States and WIV scientists proposed inserting "human-specific furin cleavage sites in a bat virus backbone." Two years later, SARS2 appeared on the WIV's doorstep. SAR2 is a bat-derived virus with a human-specific furin cleavage site.

[1] The prepared statement of Dr. Quay appears in the Appendix on page 66.

One region of SARS2, called open reading frames (ORF8), has features of forbidden gain-of-function research, asymptomatic transmission and immune system evasion. The WIV was engineering a protein related to ORF8 to have these two forbidden properties before 2019, as shown in two master's degree theses available only in Chinese.

COVID exhibits 40 percent asymptomatic transmission, unheard of for a new respiratory virus. Patients infected with an acquired deletion of ORF8 have a milder infection. Could the reduced efficacy of vaccines and natural immunity be an engineered feature? It appears likely.

Six, in December 2019, the Wuhan Institute of Virology was conducted synthetic biology research on the Nipah virus, which is 60 percent lethal in low-containment, biosafety level 2 (BSL–2), 3 facilities. The Nipah virus was in an infectious clone format. Nipah is a BSL–4 level pathogen and a Centers for Disease Control and Prevention (CDC)-designated bioterrorism agent. This is the most dangerous gain-of-function research I have ever encountered. We should assume this research continues to this day at the WIV.

I will close with five recommendations for future gain-of-function research.

Where did the pandemic begin? The competing hypotheses are a natural spillover at the Hunan Seafood Market in Wuhan and a laboratory-acquired infection. Two recent papers purport to claim the pandemic began at the Hunan Market in December 2019. There are at least six serious problems with these papers.

The most important are that in the early months no animal has ever been found to be infected with COVID–19 anywhere, including the market, and the molecular clock of SARS2 places the first human infection in the fall of 2019, long before the December market cases. All infections in the market in human were what is called Lineage B, and not the most ancestral lineage, Lineage A. I, like many other scientists, believe the market cases were a superspreader event, on this first chart here.

The earliest cluster of hospitalized patients with both the Lineage A and B virus was at the People's Liberation Army (PLA) Hospital in Wuhan. This hospital is about six kilometers from the WIV, and on Line 2 of the Wuhan subway system, as shown in this chart. All early cases are in hospitals adjacent to Line 2, and the probably that this was a chance occurrence is 1 in 68,000.

The Line 2 Covid Conduit, as I called it, includes the PLA Hospital, the WIV, the market, and the international airport. You can literally walk down into the subway system from the WIV in China and next exit outside in London, Paris, Dubai, Los Angeles, or New York, all before having any symptoms. Modeling by others suggests that the pandemic could not have occurred without the international spreading impact of Line 2.

Has gain-of-function research been useful to the COVID response or any other public health infectious disease emergency? I have found no evidence that gain-of-function research helped in either the COVID pandemic or other smaller epidemics.

We now know that an Messenger Ribonucleic acid (mRNA) vaccine can be designed within literally days of a new outbreak once the pathogen is sequenced, and large-scale manufacturing can

begin soon thereafter. This capability has now been fully road-tested and provides, in my opinion, the best defensive capability against future microbes.

It is also important to point out that gain-of-function research is a tiny sliver of all research funded by NIH. Specifically, there were over 36,000 Research Project (RO1) grants funded by NIH in 2020, the latest year with statistics. Of these, the self-described gain-of-function on potential pathogens research grants numbered only 21 in the latest funding year. Even expanding this by tenfold with a less stringent definition of gain-of-function would mean we are talking about less than 1 percent of all NIH research funding. I cannot imagine a scenario where but for this tiny research effort a new pandemic occurs.

What reforms should be considered in order to assure that such research is conducted in a safe and transparent manner? While I found no actual benefit of gain-of-function research, I believe efforts to ban it, given the vested interests of literally the entire virology community, is a hill too steep to climb. A proposal that I believe is achievable is the placement of all select agent research within the existing institutional review board structure used for human clinical trials. I believe this effort would put guardrails around the most dangerous aspects of this research, and has the added benefit of international acceptance, including in China.

My second reform would be to separate government oversight from the funding agency, and the model would be the Atomic Energy Commission.

My third suggestion is to place Western biotechnology equipment under export controls and monitoring. There are ways to build into these systems a forensic and law enforcement capability that could, for example, with probable cause and a court-ordered search warrant allow the work of any lab in the world to be scrutinized remotely.

My fourth recommendation is simple: do not put dangerous infectious disease laboratories near subways, like Line 2, where every major city in the world is accessible with the incubation period of an infection.

Finally, I am including what I call gain-of-opportunity research, going into caves where humans are seldom found, taking a bat fecal sample containing thousands of viruses, bringing those viruses back to a laboratory, and culturing the specimens where a virus might be controlled in a diverse natural environment, is now able to grow unrestricted in pure culture, provides an immense increased potential risk, a gain of opportunity for the virus.

This is the goal of the Global Virome Project, a Gates Foundation-funded, Eco-Health Alliance-associated effort. Their stated goal: collect the estimated 500,000 unknown viruses that are capable of infecting humans and bringing them back to a laboratory near you. What could go wrong?

Could I have the last slide here.

What happens if we have these hearings and nothing happens? In December 2019, we performed a remote audit, forensic examination of the Wuhan Institute of Virology and found synthetic biology experiments with the Nipah virus. As the chart shows, they had created a cloning vector with a virus the U.S. CDC defines as a bio-

terrorism agent. Nipah virus is one of the deadliest on the planet, with a greater than 60 percent lethality.

Why were they conducting this experiment? I do not know. But laboratory-acquired infection with this virus, if it became airborne, would make COVID–19 look like a walk in the park.

The work of this Committee is critical to protecting the American people as well as the people of all countries from future pandemics, manmade or natural. If we now fail to act with the knowledge we have, history will judge us poorly.

Thank you for the opportunity to speak.

Senator PAUL. Thank you, Dr. Quay. Our final witness is Dr. Kevin Esvelt. He is currently an Assistant Professor at the MIT Media Lab group, where he leads the Sculpting Evolution Group.

Dr. Esvelt received his BA in chemistry and biology from Harvey Mudd College and would later complete his PhD in biochemistry at Harvard University, as a Hertz Fellow.

While working in the laboratory of David Liu at Harvard University, Dr. Esvelt invented phage-assisted continuous evolution (PACE), which is a synthetic microbial ecosystem for rapidly evolving biomolecules. Later, during his time as a Wyss Technology Fellow, Esvelt's focus centered around the development of gene drive technology. Many of Esvelt's contributions related to the bioethics and biosafety of such gene drivers, and he is credited as the first to describe how Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) gene drives could be used to alter the traits of wild populations in an evolutionary stable manner.

In his recent work at the Sculpting Evolution Group, Dr. Esvelt and his colleagues invented the new technology known as "daisy drives," which would let communities aiming to prevent disease alter wild organisms in local ecosystems.

Throughout his career, Dr. Esvelt has been a champion of universal safeguards, transparency, raising scientific awareness of developing early warning systems to reliably detect any catastrophic biological threat, and advising policymakers on how to best mitigate global catastrophic biorisks.

Dr. Esvelt.

TESTIMONY OF KEVIN M. ESVELT, PH.D.,[1] ASSISTANT PROFESSOR OF MEDIA ARTS AND SCIENCES, MIT MEDIA LAB

Mr. ESVELT. Chair Hassan, Ranking Member Paul, Senators, thank you for the kind invitation. I have to say that I have no special insights regarding the origins of COVID. In fact, I kind of doubt that there is sufficient evidence to be conclusive in one way or the other. But our models suggest that knowing where it came from would not actually help us defend against future pandemics.

I agreed to speak to a bipartisan hearing today because this is the Emerging Threats Subcommittee, and I am increasingly concerned by our continuing failure to recognize an increasingly dire technological threat.

Leo Szilard who invented the nuclear chain reaction and launched the modern nonproliferation movement, is a scientific

[1] The prepared statement of Mr. Esvelt appears in the Appendix on page 73.

hero of mine, and he wrote, "The most important step in getting a job done is the recognition of the problem."

The problem is not our inability to agree on what does or does not constitute gain-of-function research or even whether the putative benefits of this research outweigh the risks of accidents. Rather, the problem is that we are so used to thinking of pandemics as a health and safety issue that we have missed the national security implications of identifying viruses that could be deliberately unleashed to kill millions of people.

Let me illustrate. When the genome of SARS2 was first posted online, scientists did not have to wait for physical samples of the virus to become available to begin studying it and working on countermeasures. That is because we could order synthetic deoxyribonucleic acid (DNA) corresponding to the genome of the pathogen and assemble infectious samples using freely available, step-by-step protocols.

From a biomedical perspective, that is a triumph, particularly because it only costs a few thousand dollars, and the price is plummeting. But from a security perspective, that means that thousands of researchers could gain access to a novel pandemic agent, as soon as it was identified as such.

Thankfully, we still do not know of any particularly concerning examples, that is, agents that would likely cause a pandemic if they were to be released, even at multiple sites. If we did know, then the modern-day equivalent of a terrorist, like Seiichi Endo, who is a graduate-trained virologist and doomsday cultist, who sought samples of Ebola and used chemical weapons to commit mass murder, might have well assembled them and released them in airports by now.

But if you work in public health and infectious disease you naturally want to know what the next threat might be so that you can better prepare defenses. That makes sense. That is why both United States Agency for International Development (USAID) and NIH have funded research attempting to find or create novel pandemic-capable viruses in labs all over the world.

Now we disagree on whether some of those experiments might fall into an arbitrarily defined category called gain-of-function research. We biologists disagree over what a species is. Did you know that a tiger and a lion can interbreed? But what nobody disputes is that in the hope of preventing natural pandemics both agencies seek to identify viruses that could kill as many people as a nuclear weapon, to alert the entire world to what they find, and to publicly sharing the complete genome sequences of those viruses so that skilled scientists everywhere will be able to make infectious samples.

The tragedy is that these are health experts, well-meaning health experts, who have dedicated their lives to fighting infectious disease, and they struggle to imagine anyone evil enough to deliberately cause one. They never considered that these advances in technology, which are continuing, plus a list of pandemic-capable viruses, would allow a single skilled terrorist to unleash more pandemics at once than would naturally occur in a century. No one warned them, perhaps because, as has been previously noted, they lack independent security oversight of their work.

Now it is always possible that we could save more lives by helping to prevent natural pandemics than we would lose due to deliberate acts of terrorism. But according to our numerical cost-benefit model, it is not even close, even for the best-case scenario. The reason is there are so many viruses in nature, most of which will never encounter a human. The lowest published estimate suggest that for every pandemic virus that does spill over in a century there are 100 that will never encounter a human.

That means if you identify one at random, even if we could perfectly prevent it from spilling over and causing a pandemic, that one virus, then we have a 1-in-100 chance of actually preventing a pandemic. But if there is just a 1 percent chance of deliberate misuse per year, then in that same time period we can expect to cause a pandemic. In other words, pandemic virus identification, whether it is created in the lab or whether it is just identified in the wild, is expected to kill 100 times as many people as it would save.

For 75 years, the United States successfully kept nuclear weapons out of the hands of terrorists. In the wake of a pandemic that has killed more people than could any thermonuclear explosion, it is time to start doing the same for pandemic viruses.

For starters, Congress could study the issue and release a finding on whether pandemic virus identification endangers national security. It is just that simple. Then, if necessary, reform USAID and NIH research. It could require an oversight committee of experts from security agencies to review all requests for proposals in the life sciences. It could update the Federal Select Agent Program to automatically regulate viruses at the first sign of pandemic capability, because these are the most dangerous agents out there. It could require all DNA synthesis orders to be screened for hazards.

Perhaps most important, Congress could legislate catastrophe liability, that is, liability for human-caused events that result in more than 1 million American casualties, as SARS2 has, and require general liability insurance to cover it. That would induce the market to price in the cost of negative externalities and cause professional insurance risk analysts to perform those cost-benefit analyses.

Now I am optimistic about this issue because we just need to buy time. If we can keep pandemic-capable viruses out of the hands of terrorists for a decade then we can deploy new, general-purpose defensive technologies. These range from ubiquitous sequencing that can detect any emerging threat, to perfect protective equipment for our essential workers, to low-wavelength germicidal lights, and these together could protect us from all pandemics, whether natural, accidental, or deliberate.

Pandemic proliferation is a solvable national security problem, but only if we recognize it as one. Thank you.

Senator PAUL. Thank you, Dr. Esvelt. We will start with Senator Scott from Florida.

OPENING STATEMENT OF SENATOR SCOTT

Senator SCOTT. All right. Thank you, Chair.

Dr. Esvelt, in your testimony you talk about USAID funding gain-of-function experiments through Discovery & Exploration of

Emerging Pathogens—Viral Zoonoses (DEEP VZN), the program which specifically conducts experiments geared toward pandemics and virology and Strategies to Prevent (STOP) SPILLOVER, which as you know, research is spillover between animals and humans. Can you talk about what these programs specifically are and why they may be dangerous?

Mr. ESVELT. DEEP VZN and STOP SPILLOVER are extensions of USAID's long-running PREDICT program, the goal of which was to predict pandemics, that is, to identify viruses in the wild that had a good chance of spilling over and causing a pandemic in humans. This is part of the laudable One Health program which seeks to identify essentially hotspots where viruses are likely to spill over into humans and cause a pandemic. The idea is if we find these hotspots, educate the community, teach them what to do in the event of an outbreak, then we might be able to stop it before it reaches our shores. That makes sense.

But again, they do not seem to have thought of the security issues associated with publishing a list of pandemic-capable viruses, by threat order. Now we cannot necessarily know whether a given pandemic would take off until it is spreading in humans, but there is a narrow set of laboratory experiments that can tell us, does it look like a human endemic virus, in certain traits? These are a tiny subset of all experiments that really are not very useful for anything else. They do not help with therapeutic development.

Part of PREDICT was to take samples of these viruses, bring them back to the lab, run these kinds of experiments, sequence the genomes, share them. They did not find anything particularly scary, but they found some candidates that looked fairly nasty, including at the Wuhan Institute of Virology. It is hard to know what USAID did and did not approve, but they are listed as an acknowledgement, as is NIH, on a paper that recombined those dangerous-looking but definitely not pandemic-capable viruses, and then performed experiments to see, did they look like they could plausibly cause prescription drugs.

Senator SCOTT. Do you think these programs are dangerous?

Mr. ESVELT. I think any program attempting to identify an agent that would be widely accessible and could be deliberately released to kill millions of people is pretty much the definition of dangerous, yes.

Senator SCOTT. Do you think that USAID, whose main job is to provide humanitarian aid globally, has the oversight for programs and experiments like STOP SPILLOVER and DEEP VZN, which are not humanitarian in nature?

Mr. ESVELT. I think there is a very strong humanitarian case for preventing pandemics. I think that the absence of security oversight means that USAID was probably just not aware of the security consequences of their work, and it remains to be seen whether they will decide that it is inadvisable to maintain a ranked-order list of those most threatening viruses.

Senator SCOTT. Do you think they have the oversight ability to handle this job?

Mr. ESVELT. It is unclear exactly who they are seeking advice from. My understanding is that they are seeking advice from folks

with greater security expertise, and the real question is what actions are going to come of that.

Senator SCOTT. Would these programs go through a P3CO review?

Mr. ESVELT. My understanding is that federally funded research does go through P3CO review. However, it is unclear whether the basic find-the-pathogens program, would go through such review because until you find it and at least run some characterization to determine whether or not it looks like a pandemic virus it would not necessary be regulated. As previously mentioned, due to the transparency issues with that committee it is very much unclear what their remit is and is not.

Senator SCOTT. Do you know who is on the panel for P3CO?

Mr. ESVELT. I do not.

Senator SCOTT. Is it not public?

Mr. ESVELT. My understanding is it is not public.

Senator SCOTT. Why would it not be public?

Mr. ESVELT. That is an excellent question.

Senator SCOTT. Do any of the witnesses know why it would not be public?

Mr. ESVELT. No.

Dr. QUAY. No. I know it is not public and I do not know why it is not public.

Senator SCOTT. That is part of our Federal Government, right?

Dr. QUAY. Correct.

Senator SCOTT. Do they think Americans are not smart enough to understand it?

Dr. QUAY. You will have to ask the people at the NIH.

Senator SCOTT. Do you know how they made the decision not to make the names public?

Dr. QUAY. No.

Senator SCOTT. OK. For each of you, do you think that the P3CO review is comprehensive enough on NIH grants or do you think gain-of-function grants have been approved without a P3CO review?

Senator PAUL. Let us go to Dr. Ebright. I do not want to leave him out. Then we will go to each of you. Dr. Ebright, would you like to respond to that?

Mr. EBRIGHT. Yes. As I mentioned in my summary statement, there have been only three P3CO reviews in the 4½ years that the P3CO Framework has been in effect. The majority of gain-of-function research of concern enhanced potential pandemic pathogen research supported by NIH has not undergone P3CO review. It has not undergone P3CO review for the simple reason that the NIH has not identified and flagged the proposals as subject to P3CO review and has not forwarded the proposals for P3CO review.

Senator PAUL. Let me ask the other two to respond as well.

Dr. QUAY. Yes. I think, just echoing Dr. Ebright, it has been a failure, I think, at this this point in time, and so we need to find an alternative, which is perhaps to take it out of the NIH, make the oversight outside of the agency that is funding.

Mr. ESVELT. One major problem is that gain-of-function is a terrible term. It applies to most of biotechnology in the raw. You can try to add qualifiers as you want. But it also inherently does not

catch efforts to identify perfectly natural but nevertheless highly lethal pandemic-capable viruses. It really does not matter where the thing comes from. What matters is do you know that there is a good chance that it causes a pandemic.

Again, maybe you do not think we can ever be confident more than, say, 50 percent for a given virus, but if you get a list of eight viruses that you are 50 percent confident, it is possible to make all eight, let them go, and you have pretty good odds there.

I am concerned by efforts to continue to focus on gain-of-function because it is so ill-defined, and it seems more productive to narrow in on the classes of experiments that can substantially increase our confidence that a virus is pandemic capable, wherever it comes from. I certainly echo the calls for external security oversight.

Senator SCOTT. Do you think there is appropriate oversight of existing research after it has been approved, to ensure continuous compliance?

Mr. EBRIGHT. I would say that there is not. Importantly, the P3CO Framework does not mandate compliance. If the P3CO committee makes a decision that the research may not proceed, that decision is only advisory to the funding agency. It is not mandated for the funding agency. The funding agency is free to accept or not accept the decision, and it is free to determine whether to monitor or not to monitor the progress of the work. This is a major shortcoming.

Senator SCOTT. Thank you.

Senator PAUL. I want to interject on the definition, whether gain-of-function is good definition or not. That began with the NIH. They gave us the definition and we started with that. I do think Dr. Esvelt is making some good points that we ought to be concerned with viruses that are not created but that actually come from nature that could cause pandemics. I think part of this discussion is to try to figure out where we get to.

Senator Johnson.

OPENING STATEMENT OF SENATOR JOHNSON

Senator JOHNSON. Thank you, Mr. Chairman. How long have we had gain-of-function capability? Is that with the CRISPR technology? Mr. Esvelt.

Mr. ESVELT. I should probably defer to Dr. Ebright on that.

Senator JOHNSON. Dr. Ebright, how long have we even had this capability?

Mr. EBRIGHT. The discussions have been underway since 2002 and 2003. The first examples involved reconstruction of previously eradicated or extinct pathogens. Those presented a prototype for understanding experiments that would create new health threats and the need to address them. Again, we are talking a two-decade-long discussion.

Senator JOHNSON. The technology emerged or they started discussing it and then developed the technology—which came first?

Mr. EBRIGHT. The discussions occurred as the technology emerged. It became possible to do this effectively, starting at the beginning of the millennium. The technologies have increased in sophistication and have increased in ease and decreased in cost over time.

Senator JOHNSON. Talk about the ease and the cost because I have heard it is very accessible now and it is very cheap, and a knowledgeable individual can basically do this in their garage.

Mr. EBRIGHT. That is an exaggeration. But as Dr. Esvelt has pointed out, given the genome sequence of a virus it is typically possible to reconstruct infectious particles of the virus and to do so for costs well under $10,000 in one-person month or two-person months. For an equipped laboratory, the kind of laboratory that would be present in any State program, and that is present in many research laboratories at academic institutions, this is eminently possible.

Senator JOHNSON. Reconstructing a virus is one thing, but my understanding of what, at least, the theory might be with severe acute respiratory syndrome coronavirus (SARS–CoV–2) is there is gene splicing that occurred here and some very unusual markers in this furin cleavage site and it would be beyond my comprehension exactly what that means. But talk to me a little bit about the whole gene-splicing aspect of this.

Mr. ESVELT. There are two ways to edit a virus. Nowadays the easiest way is usually to assemble it from scratch using synthetic DNA. But if it large then in some cases it is better to create the altered piece that you wish to insert into the virus and then use a tool such as CRISPR to do the insertion into the backbone.

With respect to the cost, the first virus with a chemically synthesized genome from synthetic DNA was made in 2002. Since then, the cost of gene synthesis has fallen by roughly 1,000-fold. Today the cost of ordering the components of an infectious influenza virus, for example, the synthetic DNA costs less than $1,000, and that does not require any further editing. That requires following the reverse genetics protocol, transfecting it into the cells to get the infectious virus.

I estimate that there are around 30,000 people who can do that, who have doctorates, and you can say 125 virology Ph.D.s per year are in the United States. That is roughly one-third in the world. There are probably four times as many people who have degrees in other disciplines, such as mine, who can do it. Assume a 20-year career, and that is 30,000 people, add a few technicians.

Senator JOHNSON. Was there a specific incidence or something that concerned people that caused the Pause?

Dr. QUAY. Yes. There were experiments in influenza in the Netherlands and Wisconsin that took a virus that was 90 percent lethal but not airborne and created it and made it airborne through passage in the laboratory.

Senator JOHNSON. That occurred when?

Dr. QUAY. In 2013, 2012.

Senator JOHNSON. That caught the attention of who? I mean, who was alarmed by that and instituted the Pause? I know it had to have occurred under President Obama, but which member of our health agencies?

Dr. QUAY. I think Dr. Ebright would be the best to answer that.

Senator JOHNSON. Dr. Ebright.

Mr. EBRIGHT. The proximal impetus for the Pause was a series of events, laboratory accidents at Federal laboratories that have access to and storage of potential pandemic pathogens. The accidents

included an anthrax incident at the CDC, another anthrax incident at a U.S. Army facility at Dugway in Utah, and the finding of unsecured vials labeled "smallpox virus" in an FDA NIH freezer in Maryland. Those three incidents, occurring in close succession, resulted in a hearing in the House Energy and Commerce Committee and then action by the Office of Science, Technology, and Policy. The Pause was driven, ultimately, from the White House, from the Obama Office of Science, Technology, and Policy.

Senator JOHNSON. Listening to your testimony I am assuming all three of you would agree with this statement that this research—and I would say even the mining of dangerous potential pathogens, crawl in a bat cave and try and pull these things out and bring them to a lab—there is surely no benefit that overrides the risk. We should not be doing this at all.

Dr. QUAY. Yes. I call it gain-of-function and gain-of-opportunity, where you bring a virus back. As I said, my analysis is that it has not contributed to the response to this pandemic.

Senator JOHNSON. We should not do it. I mean, we can talk about controls but the bottom line, we should not have controls so we should not even do it. Is that your position as well?

Mr. ESVELT. For balancing the potential benefits of prevention against the risk of accidents it can go either way, depending on the numbers you use for those. You can reasonably come out with either answer. When you add the misuse case, that is what absolutely blows it out of the water.

Senator JOHNSON. Dr. Ebright.

Mr. EBRIGHT. I believe a strong case can be made, or a case can be made that certain components of gain-of-function research of concern, particularly components involving pathogens that are currently in human populations, are categorically separate and more justifiable than other components of gain-of-function research of concern.

For example, currently SARS–CoV–2, the virus responsible for COVID, is present in millions of humans and is generating variant after variant. Gain-of-function research of concern on SARS–CoV–2 involving the creation of new variants and analysis of the threat posed by them arguably can be justified because this is not creating new health threats that will not arise without intervention but is addressing a health threat that is in place currently.

For that reason and for reasons like that, I believe enhancing the oversight of the research is more a more effective and more prudent strategy than simply banning it.

Senator JOHNSON. I would say improved oversight but would you also agree dramatically limit it?

Mr. EBRIGHT. Absolutely.

Senator JOHNSON. OK. Thank you, Mr. Chairman.

Senator PAUL. Senator Marshall.

OPENING STATEMENT OF SENATOR MARSHALL

Senator MARSHALL. Thank you, Mr. Chairman, and I hope America is listening today. To our witnesses let me say welcome, and I regret that none of you were able to get into the Kansas State University biochemistry program, but I certainly appreciate your credentials that are all here today.

I think it is important to not only identify the true problem but also talk about where we have been, and you all can help us fill in some of the pieces here when we talk about gain-of-function research.

It was late in 2011, when the National Science Advisory Board on Biosecurity (NSABB), which is the NIH's advisory board, stopped two scientists from publishing an influenza gain-of-function study that I believe Dr. Ebright was referring to. They stopped it because they were afraid it could afraid bioterrorists. This is 2011. Over a decade ago, scientists had figured out how to make H5N1, which is highly pathogenic avian influenza, more contagious.

In 2012, those 2 scientists and 39 others implemented a voluntary gain-of-function research pause on influenza experiments. In early 2012, Dr. Fauci encouraged all influenza scientists to pause gain-of-function, and said, and I am quoting Dr. Fauci, 2012, "It is essential we respect the concern of the public, domestically or globally, and not ask them to take the word of the influenza scientists." It is interesting to me that Dr. Fauci was focused on the messaging but he still wanted to continue the gain-of-function research.

Again, in 2012, Dr. Fauci also said, almost prophetically, that he worried about unregulated laboratories, perhaps outside the United States, doing work sloppily and leading to an inadvertent pandemic. He went on to say the accidental release is what the world is really worried about.

I go forward to 2014 now, after biosecurity accidents in United States research labs, which our witnesses have talked about, the Obama White House implemented the second gain-of-function moratorium on influenza plus MERS and SARS because of the potential risk of lab accidents and inherent gain-of-function danger. But gain-of-function still continued at the University of North Carolina, research later that we shared with Dr. Shi, the Bat Lady.

Nevertheless, clearly the U.S. Government and Dr. Fauci knew that the viral gain-of-function research was very concerning. Almost counterintuitively, while Dr. Fauci encouraged United States scientists to pause their GOF studies, Dr. Fauci offshored the paused research to China, not once but twice. In 2012, Dr. Fauci gave a new grant to Peter Daszak's EcoHealth Alliance for influenza research in China, and then again in 2014, Dr. Fauci gave another grant to Daszak for SARS research in China. Daszak partnered with who? The Wuhan Institute of Virology.

In late 2017, NIH announced a lift on the gain-of-function moratorium, what became known as the P3CO Framework, that we referred to, apparently without consultation from a Senate-confirmed State Department head or national security leadership. Also significant, there was no Office of Science and Technology Policy (OSTP) director in place and only an acting HHS Secretary at the helm.

What was the result of this? NIH essentially lifts the moratorium on their own by slipping it in-between administrations and self-policing. Today we cannot see the research record for Dr. Fauci's offshore projects because the Chinese Communist Party supposedly has EcoHealth's records, and NIH resists sharing theirs.

I will get to my question now. Dr. Ebright, could EcoHealth research in China have led to the COVID–19 pandemic and Dr. Fauci's worst fears that a lab accident in a foreign lab became reality?

Mr. EBRIGHT. Yes. Lapses in U.S. oversight of gain-of-function research of concern may have caused the current pandemic, and could cause future pandemics. The U.S. Government funded high-risk gain-of-function research and high-risk enhanced potential pandemic pathogens research at the Wuhan Institute of Virology in 2016 to 2019. The research overlapped the pause that was in effect in 2014 to 2017, and met the criteria to be paused, but was not paused.

The research also overlapped the subsequent policy, the P3CO Framework, that has been in effect from 2018 to the present, and met the criteria for Federal risk benefit review under the P3CO Framework, but did not undergo Federal risk benefit review under the P3CO Framework.

Senator MARSHALL. Thank you so much. I have to stop and point out, too, that USAID, who is knee-deep in this type of research, is part of the State Department, where they can get the security advice that they should have asked for before they cleared this with P3CO.

Certainly I believe that this virus came from Wuhan, China, and that it is a product of gain-of-function research. This is a bipartisan national security issue, like several of our witnesses have testified, that this viral gain-of-function could become, and has become a weapon of mass destruction, that this model—this is a 3–D model of what the COVID virus looks like, and this is the gain-of-function. This is the protein spike, the two units that allows this key to fit into the door perfectly and the cleavage site and all that. This became a nuclear hand grenade, is what happened.

Dr. Quay then Dr. Esvelt, considering the extreme risk of this research and the incredulous obstruction by the NIH, USAID, EcoHealth, and China, should Congress immediately pause this dangerous research?

Dr. QUAY. I think that is an appropriate step for Congress to take.

Senator MARSHALL. OK. Dr. Esvelt.

Mr. ESVELT. I think it would be somewhat dangerous to attempt to pause gain-of-function research when it is evident that that term is so malleable as to be evaded at will, and also could plausibly do damage by applying to science that is not specifically directed at potential pandemic pathogens.

Senator MARSHALL. Are there any countries that you would say we should not be doing this type of research with?

Mr. ESVELT. When it comes to identifying pandemic-capable viruses that could kill millions of people and will necessarily be shared with scientists worldwide who will be able to access them, I do not think that we should be doing it. I do not think that China should be doing it. I do not think that anyone should be doing it, because it is expected to kill 100 times as many people as it might save, even if we could perfectly prevent an identified natural virus from spilling over.

Senator MARSHALL. Thank you, Mr. Chairman. I have some more questions if we have time for later, but I yield the floor back. Thank you.

Senator PAUL. Senator Hawley.

OPENING STATEMENT OF SENATOR HAWLEY

Senator HAWLEY. Thank you, Mr. Chairman. Thanks to the witnesses for being here.

Dr. Quay, if I could start with you. You said in your written testimony that the genome of COVID has some of the hallmarks of gain-of-function research, and in particular three genomic regions you say have the signature of synthetic biology. One region has features of the two types of forbidden gain-of-function research that are associated with bioweapons development. You said in your opening remarks that you believe COVID–19 was the product of gain-of-function research and was from a lab leak from the Wuhan Institute of Virology.

My question, I guess, is, do you think China engaged in a cover-up to prevent the world from knowing the true origins of this virus and a lab leak?

Dr. QUAY. I think there is abundant evidence that they have not shared all the information they had at the time. They continue to not share information. I could give you a laundry list of 20 things that they have done, starting with a website with 21,000 viruses. On September 12th at 2 a.m., someone was in the Wuhan Institute of Virology. That had been available to virologists for a decade. It was taken offline. It has not been returned. We have asked to see it, and no one, that I know of, has ever seen it. It goes on from there.

Senator HAWLEY. Are you concerned with the continuation and expansion of Chinese gain-of-function research?

Dr. QUAY. I think I testified here that in December 2019, they were doing synthetic biology on a cloning vector of the Nipah virus, which is 60 percent lethal. We just experienced a 1 percent lethal virus. My estimates would be that that could set us back a millennium. The black plague was a 20 percent lethal event and it was 250 years for civilization to return.

Senator HAWLEY. Let me ask you this. How safe were the testing conditions at Wuhan, to your knowledge?

Dr. QUAY. I think that a lot of the Western virologists actually use the findings of that as a way to get around saying it was OK at the beginning. All of the work that I have described is being done at what is called BSL–2, 3 level, which is commonly spoken of as a dentist's laboratory level of biosafety. Maybe a little higher than that, but that is not a bad euphemism.

Senator HAWLEY. You said, I think, in your testimony, that this is the most dangerous research that you have ever encountered. What makes this particular research so dangerous?

Dr. QUAY. If you doing experiments with a pathogen that is 60 percent lethal but is not airborne, and you make it airborne in the laboratory and someone walks out with it—Nipah has a 21-day incubation period. It is perfect for wide spread without being detected. We cannot afford 10 percent lethality.

Senator HAWLEY. Yes. Dr. Ebright, let me ask you about the merits of gain-of-function research because I was struck by something you said in your written testimony. You said gain-of-function research has no civilian practical applications. From a research perspective, then, why do it? I mean, what is the value, the real value of gain-of-function research?

Mr. EBRIGHT. Not a matter of value but incentives, particularly incentives within the academic research ecosystem. Gain-of-function research of concern is fast and easy, much faster and much easier than vaccine or drug development. Gain-of-function research is publishable and gain-of-function research is fundable. With those four incentives in place—fast, easy, fundable, and publishable—the research will be performed. Eliminate any one of those incentives and it will not be.

Senator HAWLEY. Thinking about China for a second, what is China's interest in gain-of-function research?

Mr. EBRIGHT. They have witnessed the United States leading the way with gain-of-function research. Most gain-of-function research of concern performed to date has been performed either in the United States, with U.S. funding, or overseas with U.S. funding. China has wished to be part of that and has participated in gain-of-function research of concern in China with U.S. funding and has also supported gain-of-function research of concern in China entirely through Chinese programs.

Senator HAWLEY. Let me ask you this. Gain-of-function research and bioweapons, what is the connection there? I mean, what role does gain-of-function research play?

Mr. EBRIGHT. As I mentioned, there are no civilian practical applications. There are immense bioweapons practical applications. As you have heard from Dr. Esvelt, the potential pandemic pathogens that can emerge from such studies are potential weapons of mass destruction—inexpensive, accessible, easily distributed weapons of mass destruction.

Senator HAWLEY. Let me ask you about some of the things that you have commented on with regard to what NIH and Dr. Fauci have said, and frankly, the lies they have been caught in regarding the coronavirus. I want to highlight two of them.

In response to a congressional inquiry from October 2021, just last year, the NIH attempted to walk back assertions by NIH Director Collins and Fauci that NIH had not funded gain-of-function research in Wuhan. You commented at the time, saying, and I am going to quote you now, "NIH, specifically Collins, Fauci, and Daszak lied to Congress, lied to the press, and lied to the public, knowingly, willfully, brazenly. On May 11th, Dr. Fauci said the NIH and National Institute of Allergy and Infectious Disease (NIAID) categorically has not funded gain-of-function research to be conducted in the Wuhan Institute of Virology." You commented on that, saying the documents make it clear that assertions by the NIH Director, Francis Collins, and Fauci, that the NIH did not support gain-of-function research are untruthful.

Expand on that if you would. What are the implications of Dr. Fauci's continued blatant dishonesty regarding NIH's funding of gain-of-function research in Wuhan?

Mr. EBRIGHT. I stand by my statement. The statements made on repeated occasions to the public, to the press, and to policymakers by the NAIAD Director, Dr. Fauci, have been untruthful. I do not understand why those statements are being made because they are demonstrably false.

Senator HAWLEY. In my few remaining seconds here, let me ask you about an effort to shut down any kind of questioning of the origins of COVID. On February 19, 2020, a group of virologists and others published that famous letter, infamous letter, in The Lancet, which said, among other things, "We stand together to strongly condemn conspiracy theories suggesting COVID–19 does not have a natural origin."

Of course, we later found out that The Lancet letter had been organized by Peter Daszak, president of EcoHealth Alliance, who we have discussed today operated a lab in Wuhan, with a $600,000, 5-year annual grant of taxpayer dollars from Fauci's NAIAD to study bat coronaviruses.

That letter conveniently concluded by stating, "We declare no competing interests." Many people designate this letter as the first effort to quash any kind of debate about the origins of COVID–19. Do you think that labeling the lab leak theory as a conspiracy theory so early on have the effect of slowing down investigations into the origins of the virus?

Mr. EBRIGHT. It certainly had that effect, but The Lancet letter that you described was only one of two efforts to impose the false narrative that science shows SARS–CoV–2 entered humans through natural spillover, and that that is the consensus view of scientists. One of the efforts was The Lancet letter you discussed. The other effort was coordinated and orchestrated through the National Institutes of Health, through the NAIAD Director, Dr. Fauci, and the NIH Director, Dr. Collins, and resulted in the publication of an opinion article entitled "Proximal Origins of SARS–CoV–2," making the case, again, that SARS–CoV–2 could not have been a product of a research-related spillover."

Senator HAWLEY. Thank you very much. Thank you, Mr. Chairman.

Senator PAUL. Thank you. Had there not been a pandemic I think there would still be a need for this hearing. This discussion, Dr. Ebright got this started back as early as 2003, 2004. Others have commented on the danger of being able to manipulate influenza viruses to be used as either weapons or by accidental release.

But I think given that there was this pandemic, that a million Americans died, I lost friends, good friends, to the pandemic—I think we should be curious. I am perplexed by the lack of curiosity to know are there any precautions we can take, is there any kind of government oversight that we could do to try to prevent this from happening.

Now some will say, we cannot prove it came from a lab. That is, in all possibility, true, that we cannot prove it. But there are arguments to be made and examination of facts to give us an idea of whether it might have come from a lab. Even if we did not, I think that this could have come from a person in a lab handling a virus, if it was a virus out of nature, and we have discussed that as well.

I do think that we have to get to the truth of the matter of whether or not dangerous research was going on that should have been reviewable. We had a pause of gain-of-function research, but then we had research occurring during the pause that should have gone to this committee, this P3CO committee, and did not get to the committee.

I think Dr. Ebright described it well. He says that in Wuhan, in the 2016 to 2018 period, they were constructing novel chimeric SARS-related coronaviruses that combined the spike gene of bat SARS coronavirus with the rest of the genetic information of a SARS1-related virus, one that was already known to have lethality, and they found that it could efficiently infect human airway cells and exhibited up to a 10,000-fold increase in viral growth.

But when we have asked before, is this gain-of-function, we get sort of arguments and protestations that this is not gain-of-function as if this is no big deal and the experts looked at this. As we look farther into this we find that the experts never looked at this, that it is sort of a select-in kind of program to this committee. It does not go looking for dangerous research. It looks at it if you come to them and say, "Hey, I think I have gain-of-function research. Do you all want to look at my research?" And so there is this opting-in aspect to this.

But I think it is important that we get to the truth. Was there research going on in Wuhan that was dangerous? Was it funded by the NIH, and should it have gone through this committee process?

By the definition that they have given us, gain-of-function—I think I agree with Dr. Esvelt—can be better defined, and particularly if we are going to have oversight on this we are going to have to figure out what our oversight is going to be. By all means moving forward we need to ask and include the scientists to get a precise definition of what we are talking about if we want to have more oversight.

We have to look back before we look forward, not so much to assign blame but to figure out is it really necessary. Do we need to have hearings on this? Should we have follow-up hearings? Should we have legislation? If a million people died and there is a chance this came from a lab, I think without question we should. Both sides of the aisle should be looking at this.

My question, and I think it is pretty clear but I would like to go through everybody, even though Dr. Ebright has said this was gain-of-function, to each of the three witnesses, was the research, where you take the backbone of a SARS1 virus that has known lethality, and you mix it together with an unknown bat virus, S protein genes to create a new virus, was this gain-of-function according to the NIH definition and should it have been reviewed and discussed by this committee that was supposed to prevent dangerous research from going on?

We will start with Dr. Ebright.

Mr. EBRIGHT. As you mentioned, the Wuhan Institute of Virology constructed novel chimeric SARS-related coronaviruses that combined the spike gene of one coronavirus with the genetic information of another. They showed that the resulting viruses efficiently infected human airway cells and efficiently replicated in human airway cells, and they showed that the resulting viruses exhibited

up to 10,000-fold enhancement of viral growth in lungs and up to 4-fold enhancement of lethality in mice engineered to display human receptors on airway cells.

Based on those facts, and they are, indeed facts, the research was gain-of-function research of concern subject to the Pause, and was enhanced potential pandemic pathogen research subject to the P3CO Framework. Nevertheless, due to the failure of the NIH to forward the proposals for review, the work was not paused and there was no P3CO review.

Senator PAUL. Dr. Quay.

Dr. QUAY. The Wuhan Institute of Virology is unique in the entire world. Before 2019, 65 percent of all publications on coronaviruses came from that single institution. They are unique for two reasons. For almost a decade, they were going into bat caves throughout China and actually into Africa as well, 20 visits a year, and bringing these samples back to the laboratory.

On the one hand they had the largest collection of raw material backbones from nature to then do gain-of-function research on. They trained in Galveston, Texas, and in North Carolina, and were doing experiments, published experiments between 2015 and 2019.

I believe it is the confluence of those two activities, gain-of opportunity, bringing things back from bat caves, and gain-of-function research, that led to the pandemic.

Senator PAUL. Dr. Esvelt.

Mr. ESVELT. On the list of experiments you would need to perform in order to learn whether a novel virus could potentially cause a pandemic you would need to test growth in human primary cells, such as human airway epithelial cells, and you would need to test transmission in a suitable animal model.

The question is, if they were not intending to determine whether a novel recombinant event between these coronaviruses could lead to something that might kill millions of people then why were they doing it? If there was no chance that it would come up with a result that looked like it was more dangerous, what is the point? What is the scientific hypothesis?

Again, whatever you call it, what they were trying to do was identify a biological agent that has a good chance of being able to kill millions of people if released. They shared the description of what they did and they shared the genome sequence, because they thought that this would make us safer, because they think that knowing which viruses in nature might cause pandemics makes us safer.

They did not consider the security risks, and it is worth noting that both USAID and NIH funded those particular coronavirus chimeric studies. USAID, to my understanding, has since disavowed those chimeric recombination studies and announced that they will only focus on finding natural pandemic-capable viruses, which is at least a step in the right direction. But again, I would call that gain-of-function. Another reasonable scientist would say, no, that is not gain-of-function, because the term is so ill-defined.

Senator PAUL. Even beyond the term, though, would it be qualified as dangerous research that actually should have gone before this committee, the P3CO committee, and been reviewed?

Mr. ESVELT. Here is where you come back to the problem of thinking this is a health and safety issue rather than a national security issue. The question is why are we trying to identify readily accessible agents that could plausibly be used to kill millions, and will, as soon as identified, fall into the hands of all of our adversaries as well as, perhaps, individual terrorists who would want to use them?

The fundamental principle behind even wanting to do these experiments in the first place is, I think, a fundamental threat to not just national security but international security. It is hard to see why you would ever want to do this, when you think about the misuse potential. I have not seen anyone else publish a numerical model of that.

Senator PAUL. People have said, well, the closest relative that we have found is only 96 percent identical to COVID–19. This could not have come from the lab. They have also mistakenly accused those who say it came from the lab saying, oh, it came from this particular variant. I think what people who are saying that this could have come from a lab are saying is that there could also be possibly other viruses that are closer that were manipulated or that the one that is 96 percent analogous to COVID–19 could have gone through serial cell culture and become COVID–19.

I would like to ask the three of you whether or not the variant that is 96 percent analogous to COVID–19, could it, through serial passage, be transformed to COVID–19? Is it possible? Is it so far away that you cannot do it experimentally? Could you do it through gene splicing? Could it be done? Or is it something that argues that this could not have come from the lab?

We will start with Dr. Ebright.

Mr. EBRIGHT. The closest relatives are more on the order of 97 percent identical to SARS–CoV–2 genome than 96 percent. Viruses with that level of genetic difference cannot rapidly, in the time scale of weeks or months, move from their State into being a proximal progenitor of SARS–CoV–2. However, in the laboratory those viruses can be combined, at will.

They can be combined, in particular, using a method that would be described as constructing a consensus genome virus. In a constructed consensus genome virus, one takes the sequences of several related viruses, identifies the most commonly observed nucleotides at each position in these sequences, and then synthesizes the nucleic acid corresponding to the average, if you will, the consensus genome for the group of viruses.

This has been done successfully in coronaviruses. This has been done and published a decade ago in coronaviruses. That kind of research could have been done using viruses that are on the order of 96 to 97 percent identical in their genome sequences to SARS–CoV–2 and with two or three or more such virus genome sequences, one could develop a consensus.

That is just 1 of a series of potential routes by which one of the known viruses with 96 to 97 percent identity could, through a laboratory, in a relatively short time, be transformed into a progenitor of SARS–CoV–2.

Senator PAUL. Dr. Quay.

Dr. QUAY. The three sets of viruses that are closest to SARS2 are one from southern China, RTG–13, and a series of BANAL from northern Laos. As indicated there are probably 1,200 letters different in the whole 30,000-letter alphabet. In nature, that takes approximately 40 years, so the most common ancestor is about 40 years ago. But most of that can be done in a couple days in a laboratory.

However, I do not believe we currently have the starting material, the backbone on which SARS2 was found. I think it is one of the other 21,000 viruses in the database that was taken down at 2 a.m., September 12, 2019.

Senator PAUL. A great deal of information was destroyed by the Chinese.

Dr. QUAY. It was taken offline and not available. I do not know if it was destroyed.

Senator PAUL. Dr. Esvelt.

Dr. ESVELT. If a Ph.D. student proposed to take a 30,000-base-paired viral genome and attempt to passage it in the laboratory to acquire 1,000 or so mutations, I would say that is not a Ph.D. project. Go do something else. I concur with Dr. Ebright that the only way that you could get something so divergent would be to computationally design it and synthesize it, which could certainly have been done, from what dataset, and again, why? Why would you do such a thing unless you want to know what the ancestral virus was like and whether the ancestral virus was dangerous. There are basic science reasons why you might want to know where they all came from, but at the end of the day the reason why this research is of interest to us is the risk of pandemics.

Again, why would you run the tests to determine whether something was pandemic capable? They certainly ran those on all of the other coronaviruses that they found and thought might be dangerous. On the other hand, they never published anything like that, right, and presumably they would have. They published their data on the other stuff.

This is why I do not think we have enough information to know, but it was definitely not passaged in a lab from something that was maybe 7 percent——

Senator PAUL. I agree, and one of the things that tips us off that they may have been trying was in 2018, they asked for money from Defense Advanced Research Projects Agency (DARPA), and in that money they wanted to insert the furin cleavage site, which makes it highly infectious in humans. If they had the idea of that and they are asking for money, they must have thought, wow, we can do this and this is going to be a great experiment. Even our government, finally, at that point, decided not to fund that.

But what they are asking for, and this is why I think there was a "holy cow" moment when all of a sudden these scientists see the sequence of COVID–19, they say, "Oh, my goodness. Didn't they ask us, in 2018, to put that furin cleavage site in?" Lo and behold, it is there.

What I am going to ask, and I am going to finish with this and then we will have another round if some people would like to ask some other questions, is, Dr. Quay, could you sort of lay out, in as simple a fashion as possible, two or three items about the virus

that makes you think it came from—and I do not think anybody knows, with 100 percent, whether this came from a lab or whether it came from animals, but if there is some compelling evidence that suggests it could have come from the lab. Even if it was a 10 percent chance it came from a lab it is another reason for us to be concerned about having oversight on this kind of research.

Can you give me two or three things that this virus has that makes you think it is from a lab versus some of the evidence for MERS and SARS that it came from animals?

Dr. QUAY. Yes. There are three regions—the receptor binding domain, the furin cleavage site, and this protein 8 from a gene called ORF8. With respect to the receptor binding domain, if you look at what happened with SARS1, we have the virus sequenced when it first was in civet cats in the markets. It jumped into a few humans. We have the virus sequenced then. It started infecting more. Then we have the virus sequenced when human-to-human passage could occur and an epidemic occurred. You can see the progression of mutations as the virus adapted from being in civet cats and then being in humans. The first jump into humans it had only 15 percent of the mutations it needed to support an epidemic.

OK. Let us look to SARS–CoV–2. When you look at the virus that first entered the human population, out of all of the changes in the receptor binding domain there are 200 amino acids, 4,000 possible changes. There were only 17 mutations that could make it a better virus. Its receptor binding optimization was 99.5 percent, and, in fact, one of the 17 ended up being the Delta variant. That kind of optimization, juxtaposed by the fact that there were no patients in Wuhan, 36,000 blood-backed specimens tested for antibodies, not a single patient was infected.

Let us go back to SARS1. Twenty percent of all people in the markets were infected while the virus was practicing to set up an epidemic, 1 percent of the general population. We would have expected 360 in the general population in Wuhan, and we had zero.

Furin cleavage site has obviously never occurred in this related virus, the sarbecoviruses, that split from their cousins, the MERS viruses, around the time of William crossing the Channel, 1060. That was when sarbecoviruses came. There has never been a furin cleavage site, and the genetic sequence of it uses a code that has never been used, the CGG–CGG dimers, it is called, which has never been used before.

Finally, ORF8, this protein that goes into the bloodstream and suppresses interferon response so you are asymptomatic, and suppresses major histocompatibility complex (MHC) antigen presentation, so you cannot make good antibodies. This was the subject of two master's theses at the Wuhan Institute of Virology. I have found no Western scientists that worked on this location in the genome before 2019. The protein is not present in MERS. It has a 5 percent homology in SARS1. Between SARS1 and SARS2 there is a protein there but it is only 5 percent homologous.

But this master's thesis, the first one optimized its function in suppressing interferon, symptoms of fever and chills, and suppressed its antigen presentation. The second one was making synthetic biology tools so you could move it around inside genomes.

Senator PAUL. To reiterate, there have been no animals found that have COVID–19. When they did find that animals had the first SARS and MERS, they found it out within months. When they tested the animals in question, 90 percent of the animals had the SARS virus. We have not found any animals yet with COVID–19. Most viruses that come from animals first are not very infectious at first and they infect a few humans. You do not have a pandemic that does this. It smolders and then does this. During the smoldering phase you find background antibodies that people have had it, even if they do not know they had it.

When they tested the background of people who were working with the animals that had COVID they found 20 percent of them hand antibodies to having had SARS.

Dr. QUAY. SARS1, yes. Correct.

Senator PAUL. But then if we test the people in the marketplace we are not finding that. If we look at the people in the Wuhan marketplace we are not finding significant numbers that were positive, and finding almost nobody positive from the previous year that had been ill.

Dr. QUAY. No. It is zero out of 36,000.

Senator PAUL. Thank you.

Why do we not do a second round, and we will go in the same order. Senator Johnson.

Senator JOHNSON. Dr. Quay, how did we find out about the Nipah virus?

Dr. QUAY. In December 2019, five patients at a Wuhan hospital had their specimens sent—a bronchial lavage, where they stick into the throat and get a specimen—to the Wuhan Institute of Virology for sequencing. The process is to amplify it with a polymerase chain reaction (PCR) process. You make a lot of copies of what is in the specimen and you usually, inadvertently, make copies of what is going on in the laboratory.

The Wuhan Institute of Virology probably regrets, but they put a 55 million-letter database of the background information up in the gene bank, which is the NIH's database there, of everything going on. We found 20 strange things in these patient specimens—honeysuckle genes, horse viruses. Nineteen of the things we found were in publications from the laboratory over the previous 2 years. This clearly was a signal of what was going on in the lab around there.

The one thing they did not publish on was the cloning vectors of the Nipah virus. It is in the patient specimens because it was in the laboratory at the time, not in the patients, and they have never published on that at this point in time.

Senator JOHNSON. How do we know it is 60 percent lethal?

Dr. QUAY. The Nipah has had epidemics, sporadic epidemics in the belt around Africa and India, Bangladesh, and it is between 60 and 80 percent lethal in the pockets where it comes out. It is not very transmissible like Ebola so it kills 100 or 200 people and then burns out. But if they made it airborne it would be different.

Senator JOHNSON. OK. This is a virus that occurs in nature but you detected it in this database.

Dr. QUAY. I detected cloning vectors of it. They are manipulating it, which is not allowed by biological treaties.

Senator JOHNSON. That is a pretty scary scenario right there, that the Wuhan lab that might have been the originator of the coronavirus is fooling around with something far more deadly.

Dr. QUAY. Yes.

Senator JOHNSON. Obviously mum is the word.

Dr. Ebright, I am a little confused. You talked about, if we were doing gain-of-function on the current coronavirus that would be OK. That is not the indication I am getting from Dr. Esvelt here. The thing that really concerns me is—and I am not saying that you are saying this is the justification. You are just saying the reality situation is we have research centers, we have scientists that are doing this gain-of-function research, I mean very dangerous gain-of-function research, for two completely unnecessary reasons, because it is fundable and it is publishable. You have a little greed involved and you have hubris. Is that what you are saying?

Mr. EBRIGHT. The research is performed because it is fast, easy, fundable, and publishable. In the academic research ecosystem those are determinants of what research gets pursued.

Senator JOHNSON. I view that as a very corrupt research ecosystem. If that is what is driving research, and very dangerous research, it is so that you can get a funding grant just to do something for grins and then he can publish it and get the academic kudos for it. I am sorry. I just find that sick.

Mr. EBRIGHT. I would not use the term corrupt. I would not see any real difference between this than the activity of a hedge fund or the activity of a bank or a broker. The key point is that because of these incentives, self-regulation from within the community is insufficient. The scientific research community will follow the incentives. It will never effectively self-regulate on these issues.

For this reason, we have regulations with force of law for vertebrate animals research and for human subjects research. We need regulations with force of law for gain-of-function research of concern.

Senator JOHNSON. I think the difference, if it is a bank or hedge fund, they are doing things for an economic incentive, to produce something to fund a manufacturing site or fund some kind of business. I am not hearing the benefit of this research. I am seeing the risk. I am seeing the danger. I am not seeing the benefit, other than what you are saying, for the researcher itself to get money, to do something that is dangerous, and have the academic kudos for being published.

I do not know. Maybe you do not like the word "corrupt." It is completely useless. It has no benefit to society. It just has risk. It just has danger.

Dr. Esvelt, do you disagree with that assessment?

Mr. ESVELT. I think that all institutions follow their incentives, and I think that set of incentives—fast, easy, fundable, and publishable—insofar as fundable and publishable are ways of curing heart disease and cancer and forestalling aging, those are all certainly fundable and publishable, perhaps not as fundable as we would like. Certainly research into defenses against the next pandemic is right now somewhat fundable. I wish it could be more fundable. It is publishable, right? It depends on——

Senator JOHNSON. What you are talking about fundable and publishable have a beneficial reason. What I am hearing from the three of you witnesses, there is just not a benefit to this.

Mr. ESVELT. One clarification. You mentioned on endemic human viruses like SARS2, why do this. If you want to predict the next variant that is going to arise anyway, within a couple of months, one that already exists, then that is why researchers do things like deep mutational scanning of the spike protein to look and see which ones of them might have a bit of an edge in terms of maintaining infection while evading immunity a little bit, and is likely to maybe be the next variant. That then lets us design the next vaccine against the variant and guess correctly.

We have to do this with flu every year. Flu vaccines are terrible, usually, because we often guess wrong. That kind of research can help improve our guess as to what is correct.

But as soon as you make a change that would not occur in nature, then it becomes dangerous because that is something that a more pathogenic mutation could be inserted. That becomes a problem and there is no justification for doing that because nature is not going to come up with it.

Senator JOHNSON. OK. Thank you, Mr. Chairman.

Senator PAUL. Senator Marshall.

Senator MARSHALL. Thank you, Mr. Chairman, and thank you again to our witnesses for hanging in there with us.

I want to start by going back to a comment that Dr. Esvelt made, that USAID paid for gain-of-function research in China. Most people do not realize that because USAID will not give us the records, and we have been trying for over a year to get those records, which is why we are holding up one of their nominees as well. Thank you for pointing that out, Dr. Esvelt.

I am going to go to Dr. Ebright next and talk a little bit more about EcoHealth Alliance, about their record of noncompliance. They could not provide research records to NIH when NIH requested them. They did not have an adequate agreement with Wuhan Institute of Virology. They do not use appropriate rate of pay for researchers. There continues to be noncompliance with financial conflicts of interest policies.

Dr. Ebright, based upon EcoHealth Alliance's record of noncompliance, should they continue to be eligible to receive Federal funds?

Mr. EBRIGHT. Their most important aspect of noncompliance was that they were informed by the NIH, in terms and conditions in the notice of award for their grant, that in the event they encounter viral growth in their engineered coronaviruses that exceeded the growth of the parent coronaviruses by more than a factor of 10, they must immediately inform NIH and immediately stop the research. They did not do this.

That is not merely a financial violation. That is a serious hazard violation and a violation that may be connected to the origins of the current pandemic.

With that being said, it is inexplicable that they were awarded subsequent Federal awards and that they remain eligible to receive Federal awards.

Senator MARSHALL. I need to submit for the record—thank you for the answer—a couple of articles. The first, I quoted Dr. Fauci. This is an article from Science, July 2012. A handsome, young Dr. Fauci. I want to submit that for the record.[1]

My next two questions I want to submit something from The Wall Street Journal, a couple of articles as well regarding genome sequences.[2]

Senator PAUL. Without objection.

Senator MARSHALL. We will go to Dr. Quay next. You may be familiar with the genomic sequences in NIH's database—I think you spoke about them—that Chinese scientists asked to be removed and how they were, from early COVID Wuhan patients. Do you believe there could have been more data in NIH's database submitted by Chinese scientists that could hold a key to the COVID–19 origins?

Dr. QUAY. Yes. This was a really nice piece of work by Jesse Bloom at the University of Washington, who found not in the NIH database but on some Amazon web servers the actual sequences of viruses from very early patients that had been put on GenBank and then removed before they were published and made available.

The remarkable thing is, again, going to another piece of good research, the virus that first came out, the first Wuhan virus, is three mutations away from what we now know is probably the first virus, but that is a computational method. It is kind of complicated. But anyway, there is a prediction. There are three mutations that have never been seen in humans before the first virus that we have in humans. The specimens Jesse found had some of those.

We know that the Chinese have viral sequences that are ancestral to what we have, and the more of those we get, the more we will get to the bottom of this.

I will point out that these sequences were from September and October 2019, 2 months before any person in the market was sick. Again, the timing of the market spillover does not coincide with the genetics of the virus.

Senator MARSHALL. Dr. Esvelt, anything to add to that?

Mr. ESVELT. No, other than Jesse is certainly one of the foremost experts in this field, and if you want probably some of the best answers that science can give then I would recommend that you request his input.

Senator MARSHALL. Thank you. My last question. For 20 years, NIH sponsored EcoHealth's partnership with scientists from the Wuhan Institute of Virology. The Chinese scientists have bragged that their virus sample database is the largest in the world.

They took that database offline in September 2019. NIH asked EcoHealth for research records. EcoHealth told them that the records are in the custody of the Chinese government. Is it possible that the database taken offline by the Chinese government was data collected by EcoHealth and belongs to American taxpayers? Dr. Quay.

Dr. QUAY. Since the work has been funded, in part, by U.S. taxpayers, then by definition access to that would be important. I also

[1] The document submitted by Senator Marshall appears in the Appendix on page 1443.
[2] The document submitted by Senator Marshall appears in the Appendix on page 1446.

think that we do not have to rely on the Wuhan Institute of Virology for releasing that. I believe within U.S. jurisdiction there will be copies of that database. It is too valuable not to have in your own possession if you are doing research on it.

Senator MARSHALL. Do you think there is any way we can still get any of that data that is missing? I feel like, somewhere we are going to find the grandfather of COVID, or the cousin or something here in these data banks.

Why did they take them down? What is the advantage of them taking them down? Do you think we can ever find what we are missing?

Dr. QUAY. It was taken down at 2 a.m. on September 12, 2019, which is—I guess everyone works hard but that is a little suspicious to be doing it at that point in time.

I believe it contains closer precursors, and my hypothesis is it contains the one that is 50 mutations or 100 mutations, not 1,200 away, and it was too obviously a smoking gun.

But again, if you are collaborating on that and you are spending 10 years building a database inside the Wuhan Institute of Virology, you are going to mirror that database in your own facilities, which means that it has to be at EcoHealth Alliance somewhere.

Senator MARSHALL. Thank you. Dr. Esvelt, anything to add?

Mr. ESVELT. Just note that I agree with Dr. Ebright's assessment from earlier, to the extent that China is doing this research, because it is scientifically sexy and glamorous and is fast, easy, publishable, et cetera. Chinese scientists have the same incentives as Western scientists in this regard.

In fact, it is very clear that this research is not in China's strategic interest. China has no more interest than we do in handing out the blueprints to agents that can kill millions of people, including their people. This is not in the interest of any established, powerful nation. The question is, can we show leadership and persuade them of that?

Because as long as we are doing it, we are making it—we are contributing to the fact that this is seen as glamourous research. It gets published in our top-tier journals. Many Chinese scientists get bonuses for publishing in our top-tier journals. We are driving these incentives because we persist in seeing this, again, as a health and safety issue rather than a national security issue.

I think it is in our power to change it, and I think this is one issue where our interests are actually aligned with those of China, and indeed, every other established nation. These are asymmetric tools of mass death.

Senator MARSHALL. OK. Dr. Ebright, anything we did not ask you that we should have?

Mr. EBRIGHT. That I do not know, but I just wanted to agree completely with the last remark by Dr. Esvelt.

Senator MARSHALL. Thank you, and I yield back.

Senator PAUL. I want to thank everybody for being part of this hearing. I do not see this as the end. I see this as the beginning of trying to understand what caused the pandemic and trying to come up with solutions.

Each of your statements, which is longer than your testimony, will be available, for anybody who is interested.

I want to point out one thing from Dr. Ebright's testimony, for those who say, well, lab leaks should be discounted. They do not ever happen.

At one point Dr. Ebright writes, "The second, third, fourth, and fifth entries of the SARS virus"—this was the first one—"into human populations occurred as a laboratory accident in Singapore in 2003, a laboratory accident in Taipei in 2003, and two separate laboratory accidents in Beijing in 2004."

For people who say that it is a conspiracy theory that this could have come from the lab, they are discounting our history. The history has had these lab leaks. Whether or not we will ever know, with 100 percent certainty, whether this came from the lab, we have had lab leaks, and we have to realize the potential danger of these pathogens.

We did not get a great deal of time into the answer. We got a little bit into the answer, but each of the scientists we asked today were asked to let us know how we could better supervise or oversee this kind of research.

The interesting thing to me is I think they all worked independently but they came up with basically very similar solutions, an independent body outside of the funding organizations or those receiving the funding, to make the recommendations, something akin to an independent agency like a nuclear regulatory agency.

In fact, I have already been using the analogy when people ask me and say, "What is this like?" It is essentially we do not let anybody sell centrifuges to Russia or centrifuges to Iran. There are rules on the export of things. I think Dr. Esvelt, in particular, has talked about the security aspect of this.

What I would really like to come of this, and I mean this sincerely, is I would like to have a bipartisan bill that comes forward for better oversight. Maybe it is not oversight of gain-of-function but maybe it includes things that some people consider to be gain-of-function. Maybe it is more general, pandemic viruses. There are a lot of ways we can discuss it.

But the bottom line is I do not think the people doing the research are able to adequately and objectively regulate themselves, and I think having a million people die, there should be bipartisan curiosity in this, that we should be able to move forward.

My hope is that your suggestions, that you have taken the time to put in writing, you have taken the time out of your busy careers to come here, that these suggestions will become legislation. If we can get a bipartisan bill to come forward, what I would like is that our people who help us write the legislation can communicate with the three scientists here. We are willing to hear from a dozen more scientists, anybody who wants to. I want scientists to be involved in this.

But I do think that ultimately the people making the judgment should not be from one small field of science. Some have said, "Well, none of the three scientists there are virologists." I do not have a problem with virologists being part of this, but I do have a problem with them all being virologists, the same way I have a problem with behavioral science being approved for funding by all behavioral scientists. I think that there need to be people who understand science on this, but I think there also needs to be people

on the committee, as Dr. Esvelt as mentioned, that understand bioterrorism and biosecurity.

I think it should be a mixture. This is something we can talk to the scientific community about. I do not think an absolute ban is what we want. What we want is better oversight of this. But we cannot have something where three projects have been looked at in the last 7 years. That means they are not looking.

The fact that they did not look at what went on in Wuhan, and then some of the folks I asked in committee about this were saying, "Oh, our scientists looked at it and approved it," even that is not really true. They did not look at the research. They just ignored the research. It did not go before the committee. They have not been honest.

If we want trust in public health, trust in government, trust in science, trust in research, trust in the NIH, and trust in the grants that we give our universities, billions of dollars, we need to have transparency and honesty. We cannot have a committee where the people are cloaked in secret. I mean, what is this? This is completely insane.

I think we have made some progress. I want to move forward, and I, for one, am open to work with any Democrat in the Senate to make this a bipartisan bill, and to make it an evenly-keeled where all the voices are heard, that we do not rashly create any legislation that would hamper science, but we create something that would have oversight and might save lives.

I truly think that a million people died in our country, six million people died, and I think it was from a lab leak. I think it is something that we need to have precautions against. I think it was accidental, by the way. But I think if we do not do anything, what if this gets in the hands of somebody who actually really wants to harm America or the world, or just some psychopath? What could happen?

Right now we are doing nothing and have changed no behavior. We have had this pandemic and we have changed not one bit of behavior. I think it is about time that we do get together, that we are all curious, and that we do not make this about Republicans and Democrats but make this about how we, as a people, come together to try to make this world a better place.

Thank you all for appearing.

[Whereupon, at 4:13 p.m., the Subcommittee was adjourned.]

APPENDIX

ETSO Subcommittee Hearing: Revisiting Gain of Function Research: What the Pandemic Taught Us and Where Do We Go From Here?

August 3, 2022

Opening Statement of Ranking Member Paul

Good afternoon and welcome to each of our panelists. Thank you for joining us.

The purpose of this hearing by the Subcommittee on Emerging Threats and Spending Oversight is to discuss, as our name implies, the emerging threat posed by gain of function research.

We will hear from a panel of three witnesses, all of whom are extraordinarily accomplished experts in the scientific community. We are grateful for that work, and we are grateful to each of you for taking the time to appear here with us this afternoon.

Gain of function research is a controversial scientific research method involving the manipulation of pathogens to give them a new aspect or ability, such as making viruses more transmissible or dangerous to humans. Despite all we have learned about the potential risks of this particular method of research, this is the first congressional hearing on the subject.

Today we will discuss 1.) what gain of function research entails, 2.) how gain of function research is defined, and 3.) whether the definition of gain of function research is applied consistently by the Department of Health and Human Services P3CO review committee, which is responsible for evaluating the risks & benefits of such research.

We'll also discuss how this P3CO committee operates. The P3CO approves or denies projects from receiving federal funding based on whether the pathogen is considered to be a "credible source of a potential future human pandemic," and if "the potential risks as compared to the potential benefits to society are justified." In other words, a project is not gain of function if the review committee is unsure if a recombinant virus will create a future pandemic. Such broad criterion gives one sole committee, comprised of an unknown group of bureaucrats, the power to spend millions of taxpayer dollars on a single preemptive guess – with potentially devastating consequences.

Today we will also consider whether gain of function research was being performed at the Wuhan Institute of Virology. First, no one – not myself or anyone I'm aware of – argues that a recombinant super-virus that has been published in scientific journals is COVID-19 or a close relative. If COVID-19 leaked from the Wuhan lab, it would be a laboratory-created virus that the Wuhan scientists have not yet, and are unlikely ever, to reveal.

I maintain that the techniques that the NIH funded in Wuhan to create enhanced pathogens may also have been used to create COVID-19. The American people deserve to know how this pandemic started, and to know if the NIH funded research that may have caused this pandemic.

Gain of function research has the potential to unleash a global pandemic that threatens the lives of millions, yet this is only the first time the issue has been discussed in a Congressional committee. I am sure each member of this committee as well as the full Senate can agree that we need stronger government oversight of how our tax dollars are being used to finance experimenting with mutating fatal diseases with outstandingly high mortality rates.

Again, I thank each of our distinguished witnesses for being here today, and I thank Senator Hassan for working with me to convene this hearing.

Chairman Peters Statement for the Record
Subcommittee on Emerging Threats and Spending Oversight Hearing
"Revisiting Gain of Function Research: What the Pandemic Taught Us and Where Do We Go From Here"
August 3, 2022

- This hearing was requested by Ranking Member Rand Paul, and all witnesses were solely picked by the minority.
- There was no involvement by members of the majority.
- In order to ensure the committee record fully reflects the hearing topic, I would like to submit the following documents for the record:
    - Stakeholder Letter on Pathogen Research and Biosecurity, Letter to Honorable Rosa DeLaura, Honorable Kay Granger, Honorable Tom Cole, July 14, 2021.
    - Stakeholder Letter on Pathogen Research and Biosecurity, Letter to Honorable Nancy Pelosi, Honorable Kevin McCarthy, Honorable Chuck Schumer, Honorable Mitch McConnell, April 8, 2022.
    - Pekar JE, Magee A, Parker E, et al. *The molecular epidemiology of multiple zoonotic origins of SARS-CoV-2*. Science. (Jul. 26, 2022).
    - Worobey M, Levy JI, Serrano LM, et al. *The Huanan Seafood Wholesale Market in Wuhan was the early epicenter of the COVID-19 pandemic*, *Science*, (Jul. 26, 2022).

Written Testimony of Richard H. Ebright

Board of Governors Professor of Chemistry and Chemical Biology, Rutgers University

Laboratory Director, Waksman Institute of Microbiology

Submitted for the Record to the US Senate Committee on Homeland Security

Subcommittee on Emerging Threats and Spending Oversight

For the Hearing "Revisiting Gain of Function Research"

August 3, 2022

Chair Hassan and members of the Committee:

Thank you for inviting me to discuss gain-of-function research and its oversight. I am Board of Governors Professor of Chemistry and Chemical Biology at Rutgers, The State University of New Jersey, and Laboratory Director at the Waksman Institute of Microbiology. I direct a biomedical research laboratory and serve as project leader on two National Institutes of Health (NIH) research grants. I conduct research on the mechanism of bacterial RNA synthesis and on the development of new antibacterial therapeutic agents able to treat bacterial infections resistant to current drugs. My research involves both priority public health bacterial pathogens (e.g., the pathogens responsible for Staph infections, Strep infections, and tuberculosis) and priority biodefense bacterial pathogens (e.g., the pathogens responsible for anthrax, plague, and tularemia). I am a member of the Institutional Biosafety Committee of Rutgers University, and I have been a member of the Working Group on Pathogen Security of the state of New Jersey, the Controlling Dangerous Pathogens Project of the Center for International Security Studies, and the Biosecurity Advisory Board of the Center for Civilian Biodefense. Here, I discuss the definition of gain-of-function research of concern, risks and benefits of the research, US oversight of the research, and recommended steps to strengthen US oversight of the research. In my written comments, I also include an appendix addressing the origin of SARS-CoV-2 and the possibility that lapses in US oversight of gain-of-function research of concern contributed to the origin of SARS-CoV-2. My assessments are based on information in published NIH, Health and Human Services (HHS), Office of Science and Technology Policy (OSTP), and Congressional Research Service (CRS) documents, on published press reports, on published scientific papers, and on my knowledge of biosafety and biosecurity standards for work with pathogens.

Gain-of-function research of concern

Definition

Gain-of-function research of concern is defined as research activities reasonably anticipated to increase a potential pandemic pathogen's transmissibility, pathogenesis, ability to overcome immune response, or ability to overcome a vaccine or drug. Some definitions also include research activities reasonably anticipated to reconstruct an extinct or eradicated potential pandemic pathogen.

Gain-of-function research of concern involves the creation of *new health threats*--health threats that did not exist previously and that might not have come to exist by natural means for tens, hundreds, thousands, or tens of thousands of years.

Most gain-of-function research of concern to date has been performed in the US with US funding or overseas with US funding.

Gain-of-function research of concern is a small part of the biomedical research enterprise (less than 0.1% of all biomedical research and less than 1% of virology). However, because gain-of-function research of concern can cause pandemics, this small part of the biomedical research enterprise is highly consequential and requires effective oversight.

Risks

Gain-of-function research of concern poses high--potentially existential--risks. Gain-of-function research of concern poses both material risks and information risks.

Gain-of-function research of concern poses *material risks* by creating new or enhanced potential pandemic pathogens. If a resulting new potential pandemic pathogen is released into humans, either by accident or deliberately, this can cause a pandemic.

Gain-of-function research of concern poses *information risks* by providing information on the construction and properties of new potential pandemic pathogens. Publication of the research provides instructions--step-by-step "recipes"--that can be used by a rogue nation, organization, or individual to construct a new potential pandemic pathogen and release it to cause a pandemic. With current biotechnology, the technical means to do this are within the reach of most nations. With improvements in biotechnology in the next decade, the technical means to do this likely also will be within the reach of most sub-state organizations and individuals.

The risks posed by gain-of-function research of concern are *inherent risks*. In some cases, the risks can be mitigated, but in no case can the risks be eliminated.

Benefits

Gain-of-function research of concern provides limited benefits.

Gain-of-function research of concern can advance scientific understanding and, in some cases, can do so more quickly than alternative research strategies.

However, gain-of-function research of concern has no civilian practical applications. In particular, gain-of-function research of concern is not needed for, and does not contribute to, the development of vaccines and drugs. (Companies develop vaccines and drugs against pathogens that exist and circulate in humans. Not against pathogens that do not yet exist and do not yet circulate in humans.)

Gain-of-function research of concern is performed because it is easy and fast (much faster and much easier than vaccine or drug development) and because, it is fundable and publishable. Not because it is needed.

Risk-benefit assessment and risk-mitigation review

Because gain-of function research of concern poses high--potentially existential--risks and provides limited benefits, the risk-benefit ratio for the research almost always is unfavorable and in many cases is extremely unfavorable.

Therefore, it is imperative that gain-of function research of concern be subject to national- or international-level oversight to ensure that, before the research is started, risk-benefit assessment is performed, risk-benefit profiles are acceptable, and mitigable risks are mitigated..

Effective oversight includes three components:

First, research proposals that include gain-of function research of concern must be identified

Second, a risk-benefit assessment and a risk-mitigation review must be performed. This entails enumerating anticipated risks, enumerating anticipated benefits, weighing risks and benefits, and reaching a decision either (i) to proceed as proposed, (ii) to proceed with additional risk mitigation, or (iii) not to proceed.

Third, compliance with the decision from the risk-benefit assessment and risk-mitigation review must be mandated, monitored, and enforced.

US oversight of gain-of-function research of concern

US oversight, before 2014

Before 2014, there was no national-level US oversight of gain-of-function research of concern.

US oversight, 2014-2017

In 2014-2017, there was a moratorium on HHS funding for "selected gain of function research," defined as research activities reasonably anticipated to increase transmissibility or pathogenicity of influenza, SARS, or MERS viruses. The policy was referred to as the "US Government Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS Viruses," or, for short, as the "Pause." (https://www.phe.gov/s3/dualuse/documents/gain-of-function.pdf).

Under the Pause, 18 projects were paused.

However, at least 7 of the 18 projects that were paused were allowed to re-start almost immediately (based on a certification by the NIH Director that the projects were "urgently necessary to protect the public health or national security"). More important, other projects that met the definition for coverage under the Pause--including a project on engineering of SARS- and MERS-related coronaviruses by EcoHealth Alliance and the Wuhan Institute of Virology--were not paused, due to the failure of the NIH to identify all covered projects

US oversight, 2018-present

In 2018-present, there has been a requirement for HHS-Secretary-level risk-benefit assessment prior to awarding HHS funding for "research involving enhanced potential pandemic pathogens,"

defined as research activities reasonably anticipated to increase transmissibility or pathogenicity of a potential pandemic pathogen. The policy is referred to as the "HHS Framework for Research Involving Enhanced Potential Pandemic Pathogens," or, for short, as the "P3CO Framework" (https://www.phe.gov/s3/dualuse/documents/p3co.pdf).

Under the P3CO Framework, covered projects are to be identified by HHS funding agencies (i.e., the NIH and the CDC), and covered projects are to be forwarded to, and reviewed by, a committee appointed by the HHS Secretary (i.e., the HHS P3CO Committee).

The P3CO Framework applies to funding for proposed research and operates before funding and conduct of the research (not after completion of the research). Accordingly, identification of covered projects coverage under the policy is based on proposed research and evaluates "reasonably anticipated" results of the proposed research (not results after completion of the research). The "reasonably anticipated" standard employed by the policy is equivalent, in all respects, to the "reasonable person" standard employed in US administrative and civil law.

The definitions of the research activities covered by the P3CO Framework, and the definitions of research activities exempted from the P3CO Framework, are clear. They are as clear as in any US statute or rule having a "reasonable person" standard. The policy covers research activities reasonably anticipated to increase the transmissibility or the pathogenicity of a potential pandemic pathogen, including research activities in which neither the pathogen to be modified nor the enhanced pathogen to be generated is known to infect humans.

In principle, the P3CO Framework provides for risk-benefit assessment and risk-mitigation review for gain-of-function research of concern. *In practice, however, the P3CO Framework largely has existed only on paper.* In the four-and-one-half years since the policy was

announced, *only three projects have been reviewed*: two projects that had been carried over from the Pause, and one new project. Most covered projects--including the project on engineering of SARS- and MERS-related coronaviruses by EcoHealth Alliance and the Wuhan Institute of Virology--were not reviewed, due to a failure by the NIH to identify covered projects and to forward covered projects to the HHS P3CO Committee for review. In addition, the HHS P3CO Committee has operated with complete non-transparency and complete unaccountability. The names and agency affiliations of its members have not been disclosed, its proceedings have not been disclosed, and even its decisions have not been disclosed.

Shortcomings in US oversight of gain-of-function research of concern

US oversight of gain-of-function research of concern has grave shortcomings:

- Responsibility for oversight is assigned to federal agencies that perform research and/or fund research. This constitutes an inherent conflict of interest.
- Oversight applies only to HHS-funded research.
- Oversight is not codified in regulations with force of law, and, as a result, compliance is neither mandated, monitored, nor enforced.
- Oversight has been nullified by the failure of federal research funding agencies to identify covered projects and to forward them for review
- Oversight has been not been transparent and accountable, neither at the level of the federal research funding agencies nor at the level of the HHS P3CO Committee .

Strengthening US oversight of gain-of-function research

Rationale

Lapses in US oversight of gain-of-function research of concern may have caused the current pandemic (see Appendix 1), and could cause future pandemics The US government funded high-risk gain-of-function research and high-risk enhanced potential pathogen research at the Wuhan Institute of Virology in 2016-2019. The research overlapped the US Government Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS Viruses (the Pause) that was in effect in the 2014 to 2017, and met the criteria to be paused, but was not paused. The research also overlapped the HHS Framework for Research Involving Enhanced Potential Pandemic Pathogens (the P3CO Framework) that has been in effect in 2018 to the present, and met the criteria for federal risk-benefit review under the P3CO Framework, but did not undergo federal risk-benefit review under the P3CO Framework. The research was performed at biosafety level 2--a biosafety level that is inadequate for research with potential pandemic pathogens. The research may have generated SARS-CoV-2 or a proximal progenitor, and an accident in the research may have been responsible for entry of SARS-CoV-2 or a proximal progenitor into the human population.

These facts--and these statements indeed are facts--are an indictment of the current system of US oversight of gain-of-function research of concern and are a testament that strengthening US oversight of gain-of-function research of concern is essential.

Moving forward, any effective system of US oversight of gain-of-function research of concern must address the shortcomings of the current system:

Recommendations

- **Responsibility for US oversight of gain-of-function research of concern should be assigned to a single, independent federal agency that does not perform research and does not fund research. The oversight of research on fissionable materials by the Nuclear Regulatory Commission provides a precedent and a model.**

- **US oversight of gain-of-function research of concern should cover all US and US-funded research, irrespective of funding source, classification status, and research location.**

- **US oversight of gain-of-function research of concern should be codified in regulations with force of law and should be mandated, monitored, and enforced--in the same manner that US oversight of human-subjects research and vertebrate-animals research is codified in regulations with force of law and is mandated, monitored, and enforced.**

- **The US should call on other nations to adopt similar systems of oversight of gain-of-function research of concern.**

- **The US should call for an additional, international-level layer of oversight for the highest-risk, highest-consequence subset of gain-of-function research of concern. The oversight of research on smallpox virus by the World Health Organization Advisory Committee on Variola Virus Research provides a precedent and a model.**

Appendix 1: Origins of SARS-CoV-2

SARS-CoV-2 may have entered humans through a research-related accident.

The genome sequence of SARS-CoV-2 indicates that its progenitor was a bat coronavirus.

Bat coronaviruses are present in nature in multiple parts of China. Therefore, the first human infection could have occurred as a natural accident, with a virus passing from a bat to a human, possibly through another animal. There is clear precedent for this. The first entry of the SARS virus into the human population occurred as a natural accident in a rural part of Guangdong province in 2002.

But bat coronaviruses also are collected and studied by laboratories in multiple parts of China, including the Wuhan Institute of Virology. Therefore, the first human infection also could have occurred as a research-related accident, with a virus accidentally infecting a field-collection staffer or a laboratory staffer, followed by transmission from the staffer to the public. There also is clear precedent for this. The second, third, fourth and fifth entries of the SARS virus into human populations occurred as a laboratory accident in Singapore in 2003, a laboratory accident in Taipei in 2003, and two separate laboratory accidents in Beijing in 2004.

At this point in time, there is no scientific or other secure basis to assign relative probabilities to the natural-accident hypothesis and the research-related-accident hypothesis. Nevertheless, there are three lines of circumstantial evidence that should be noted:

First, the outbreak occurred in Wuhan, a city of 11 million persons that is more than 800 miles from, and outside the flight range of, known bat colonies with SARS-related coronaviruses.

Second, the outbreak occurred in Wuhan, on the doorstep of the laboratory that conducts the world's largest research project on bat viruses, that has the world's largest collection of bat viruses, and that possessed and worked with the bat virus that, at the time SARS-CoV-2 emerged, was the world's closest known relative of SARS-CoV-2. The laboratory actively searched for new bat viruses in bat colonies in caves in remote rural areas in Yunnan province, brought those new bat viruses to Wuhan, and then mass-produced, genetically manipulated, and studied those new bat viruses, year-round, inside Wuhan.

Third, the bat-SARS-related-coronavirus projects at the Wuhan Institute of Virology, including projects involving the construction and initial characterization of novel chimeric SARS-related coronaviruses having enhanced viral growth and enhanced lethality, used personal protective equipment (usually just gloves; sometimes not even gloves) and biosafety standards (usually just biosafety level 2) that would pose high risk of infection of field-collection or laboratory staff upon contact with a virus having the transmission properties of SARS-CoV-2.

SARS-CoV-2 may have entered humans through US-funded gain-of-function research and lapses in US oversight of gain-of-function research.

The research at the Wuhan Institute of Virology included activities that met the definition of "selected gain of function research" in the US policy in effect in 2014-2017 and that met the definition of "enhanced potential pandemic pathogen research" in the US policy in effect in 2018-present. Using US funding, provided by the NIH in 2014-2019, the Wuhan Institute of Virology: (1) constructed novel chimeric SARS-related coronaviruses that combined the spike gene of one bat SARS-related coronavirus with the rest of the genetic information of another bat SARS-related coronavirus, (2) showed that resulting viruses efficiently infected human airway

cells and efficiently replicated in human airway cells, and (3) showed that the resulting viruses exhibited up to 10,000-fold enhancement of viral growth in lungs, and up to 4-fold enhancement of lethality, in mice engineered to display human receptors on airway cells ("humanized mice").

Although this research met the definition of gain-of-function research in the US policy in effect in 2014-2017 (the Pause) and exceeded--by more three orders of magnitude--the threshold set by the NIH for enhancement of viral growth that should trigger immediate cessation of work, and although the NIH was informed of project objectives and results in annual project progress reports in 2016-2018, the NIH failed to flag the project as being covered by the policy, failed to pause the project as required by the policy, and failed to stop the project as required by the Terms and Conditions of the grant.

Although the research also met the definition of enhanced potential pandemic pathogen research in the US policy in effect in 2017-present (the P3CO Framework), and although the NIH was informed of project objectives and results in a proposal for renewal of the grant for 2019-2024, the NIH failed to identify the project as being covered by the policy, and failed to forward the proposal to the HHS Secretary for the risk-benefit assessment required by the policy.

On October 20, 2021, in response to a request from the Ranking Member of the House Oversight Subcommittee, the NIH Acting Director, Lawrence A. Tabak, D.D.S., Ph.D., released a letter on NIH-funded research on bat SARS-related coronaviruses conducted at the Wuhan Institute of Virology and Wuhan University in 2014-2019 (https://www.documentcloud.org/documents/21674679-tabak-letter-to-comer-oct-20-2021). The Tabak letter addressed: (1) NIH funding under grant AI110964, awarded by the NIH to EcoHealth Alliance with subcontracts to the Wuhan Institute of Virology and Wuhan University;

(2) the virus WIV1 SHC014 S (mis-rendered as "SHC014 WIV1"), a virus constructed and characterized in Wuhan using NIH funding under NIH grant AI110964;; and (3) the possibility that the virus WIV1 SHC014 S was a proximal progenitor of SARS-CoV-2.

WIV1 SHC014 S is a novel chimeric SARS-related coronavirus that combines the spike gene of one bat SARS-related coronavirus with the rest of the genetic information of another bat SARS-related coronavirus. It is an artificial, laboratory-constructed virus that has no counterpart in viruses that circulate in nature. It is one of at least three artificial, laboratory-constructed chimeric coronaviruses that were constructed by EcoHealth Alliance and its Wuhan partners using NIH funding and that were shown to infect human airway cells, to replicate in human airway cells, and to exhibit 10,000-fold higher viral growth and higher lethality than the parental natural coronavirus in infection studies in mice engineered to display human receptors on airway cells ("humanized mice"; https://theintercept.com/document/2021/09/08/understanding-the-risk-of-bat-coronavirus-emergence/; https://republicans-oversight.house.gov/wp-content/uploads/2021/10/Year-5-EHAv.pdf).

The year-4 progress report for the first 5-year term of the NIH grant (submitted to the NIH in March 2018) and the proposal for the second term 5-year term of the NIH grant (submitted to the NIH in November 2018) reported the construction of the three chimeras, the 10,000-fold enhanced viral growth in humanized mice of the three chimera, and the enhanced pathogenicity in humanized mice of one of the three chimeras (https://theintercept.com/document/2021/09/08/understanding-the-risk-of-bat-coronavirus-emergence/).

The year-5 proposal for the first 5-year term of the NIH grant (submitted to NIH in August 2021, more than two years overdue, and released to the Ranking Member of the House Oversight Subcommittee together with the Tabak letter) reported that the chimeras exhibited enhanced viral growth in brains as well as in lungs of humanized mice, and exhibited 2- to 4-fold increased lethality in humanized mice (https://republicans-oversight.house.gov/wp-content/uploads/2021/10/Year-5-EHAv.pdf).

The Terms and Conditions of the first 5-year NIH grant stated (https://theintercept.com/document/2021/09/08/understanding-the-risk-of-bat-coronavirus-emergence/):

> Per the letter dated July 7, 2016 to Mr. Aleksei Chmura at EcoHealth Alliance, should any of the MERS-like or SARS-like chimeras generated under this grant show evidence of enhanced virus growth greater than 1 log over the parental backbone strain you must stop all experiments with these viruses and provide the NIAID Program Officer and Grants Management Specialist, and Wuhan Institute of Virology Institutional Biosafety Committee with the relevant data and information related to these unanticipated outcomes.

The term "1 log" means "a factor of 10". EcoHealth Alliance and its Wuhan partners created novel chimeras of SARS-related coronaviruses that showed enhanced viral growth by greater than a factor of 10,000...which exceeded, *by three orders of magnitude*, the trigger point for stopping work and reporting results to NIH under the Terms and Conditions of the NIH grant.

The Tabak letter confirms that research reported in the reported in the year-4 and year-5 progress reports of the first 5-year grant and in the renewal proposal for the second 5-year grant--research

in Wuhan that generated a potential pandemic pathogen with a greater than 10,000-fold enhanced viral growth, enhanced pathogenicity, and enhanced lethality in humanized mice-- occurred. The Tabak letter thus confirms that NIH funds supported gain-of-function research of concern and construction and characterization of an enhanced potential pandemic pathogen--a pathogen reasonably anticipated, indeed likely, to have enhanced transmissibility and/or pathogenicity in humans--in Wuhan.

The Tabak letter reveals that EcoHealth Alliance and it Wuhan partner failed to report to NIH in a timely manner that they had obtained evidence of enhanced viral growth greater than 1 log over the parental backbone strain. Thus the Tabak letter confirms that EcoHealth Alliance and its Wuhan partner violated the Terms and Conditions of the first 5-year grant,

The Tabak letter also reveals that EcoHealth Alliance failed to submit the year-5 progress report for the first 5-year grant report until more than two years after the submission deadline. Thus the Tabak letter also confirms that EcoHealth Alliance and its Wuhan partner again violated the Terms and Conditions of the first 5-year grant,

The Tabak letter correctly states that WIV1 SHC014 S and the other novel chimeric SARS-related viruses reported to the NIH by EcoHealth Alliance and its Wuhan partners in their 2018 grant progress report and 2018 grant renewal proposal are insufficiently closely related to SARS-CoV-2 to have served as a proximal progenitor of SARS-CoV-2.

However, the Tabak letter leaves unstated the crucial fact that the NIH has received no information on novel chimeric SARS-related viruses constructed by EcoHealth Alliance and its Wuhan partners subsequent to the 2018 grant progress report and 2018 grant renewal proposal., and therefore that the NIH cannot rule out the possibility that the project created a proximal

progenitor of SARS-CoV-2, and cannot even rule out the possibility that the project used NIH funding to create a proximal progenitor of SARS-CoV-2.

The Tabak letter also leaves unanswered the questions of why the NIH, which was provided with relevant data in March of 2018 and again in November of 2018, and which became aware of the failure to submit the year-5 progress report in 2019: (1) failed to act on the violations of the Terms and Conditions of the first 5-year grant, (2) awarded a second 5-year grant period despite the violations of the Terms and Conditions of the first 5-year grant, (3) awarded a second 5-year grant period for a project that proposed continuation of enhanced potential pandemic pathogen research--specifically proposing to construct and characterize additional novel chimeric SARS-related coronaviruses--without forwarding the proposal for HHS-level risk-benefit review as required under the HHS P3CO Framework, and (4) falsely asserted that NIH funding had not supported gain-of-function research or enhanced potential pandemic pathogen research in Wuhan.

U.S. Government Gain-of-Function Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS Viruses

October 17, 2014

U.S. Government Gain-of-Function Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS Viruses

Gain-of-function studies, or research that improves the ability of a pathogen to cause disease, help define the fundamental nature of human-pathogen interactions, thereby enabling assessment of the pandemic potential of emerging infectious agents, informing public health and preparedness efforts, and furthering medical countermeasure development. Gain-of-function studies may entail biosafety and biosecurity risks; therefore, the risks and benefits of gain-of-function research must be evaluated, both in the context of recent U.S. biosafety incidents and to keep pace with new technological developments, in order to determine which types of studies should go forward and under what conditions.

In light of recent concerns regarding biosafety and biosecurity, effective immediately, the U.S. Government (USG) will pause new USG funding for gain-of-function research on influenza, MERS or SARS viruses, as defined below. This research funding pause will be effective until a robust and broad deliberative process is completed that results in the adoption of a new USG gain-of-function research policy[1]. Restrictions on new funding will apply as follows:

> *New USG funding will not be released for gain-of-function research projects that may be reasonably anticipated to confer attributes to influenza, MERS, or SARS viruses such that the virus would have enhanced pathogenicity and/or transmissibility in mammals via the respiratory route. The research funding pause would not apply to characterization or testing of naturally occurring influenza, MERS, and SARS viruses, unless the tests are reasonably anticipated to increase transmissibility and/or pathogenicity.*

In parallel, we will encourage the currently-funded USG and non-USG funded research community to join in adopting a voluntary pause on research that meets the stated definition.

The deliberative process that will ensue during the period of the research pause will explicitly evaluate the risks and potential benefits of gain-of-function research with potential pandemic pathogens. The presumptive benefits that are generally identified in pursuing this type of research are stated in terms of enhanced ability for earlier awareness of naturally emerging dangerous pandemic pathogens or in the development of medical products in anticipation of such emergence.

However the relative merits of gain-of-function experimental approaches must be compared ultimately to potentially safer approaches. The deliberative process will offer recommendations for risk mitigation, potential courses of action in light of this assessment, and propose methodologies for the objective and rigorous assessment of risks and potential benefits that might be applied to the approval and conduct of individual experiments or classes of experiments. Although the gain-of-function studies that fall within the scope of research subject to the funding pause will be a starting point for deliberations, the suitability of other types of gain-of-function studies will be discussed. It is feasible that the discussion could lead to suggestions of broadening the funding pause to include research with additional pathogens,

[1] An exception from the research pause may be obtained if the head of the USG funding agency determines that the research is urgently necessary to protect the public health or national security.

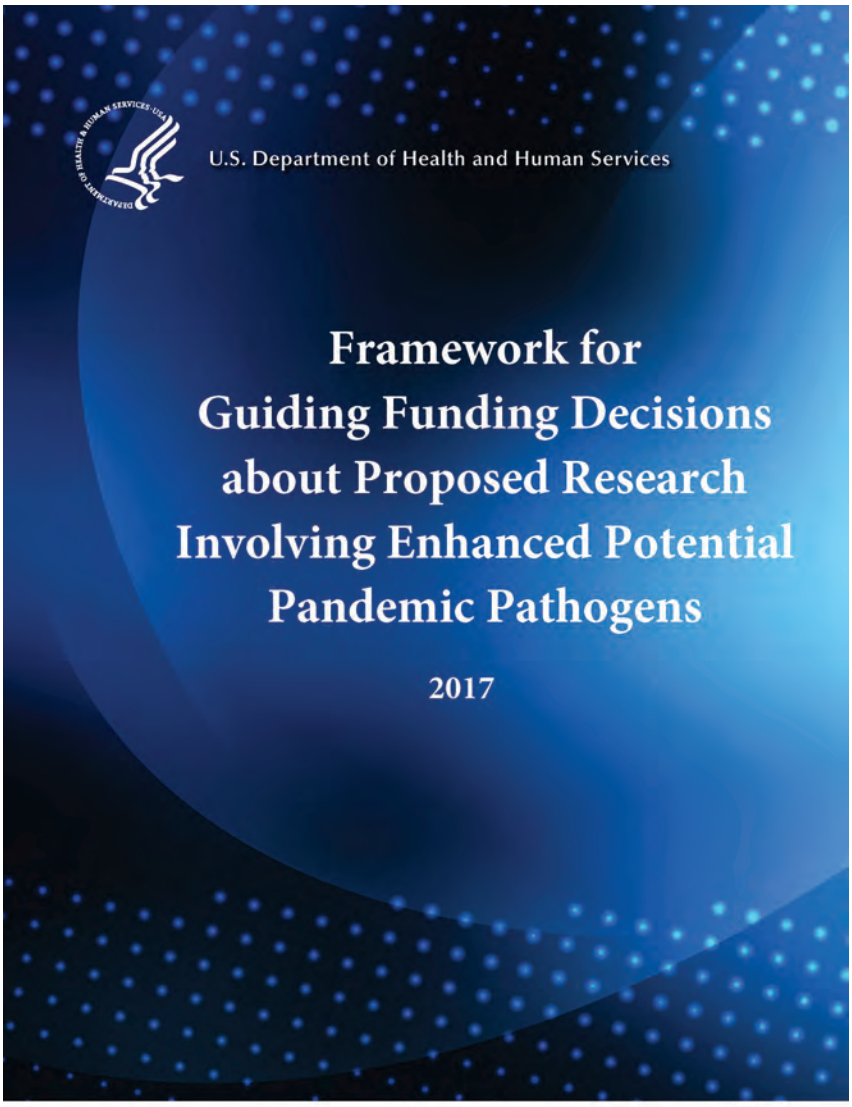
however, federal Departments and Agencies who fund, support, or perform research should be consulted prior to any additional pathogens being added to the scope of the funding pause.

The deliberative process is envisioned to be time-limited, to involve two distinct, but collaborating, entities, and to be structured to enable robust engagement with the life sciences community. As a first step, the National Science Advisory Board for Biosecurity (NSABB) will be asked to conduct the deliberative process described above and to draft a set of resulting recommendations for gain-of-function research that will be reviewed by the broader life sciences community. The NSABB will serve as the official federal advisory body for providing advice on oversight of this area of dual use research, in keeping with federal rules and regulations.

As a second step, coincident with NSABB recommendations, the National Research Council (NRC) of the National Academies then will be asked to convene a scientific conference focused on the issues associated with gain-of-function research and will include the review and discussion of the NSABB draft recommendations. This NRC conference will provide a mechanism both to engage the life sciences community as well as solicit feedback on optimal approaches to ensure effective federal oversight of gain-of-function research. The life sciences community will be encouraged to provide input through both the NRC and NSABB deliberative processes.

The NSABB, informed by NRC feedback, will deliver recommendations to the Secretary of Health and Human Services, the Director of the National Institutes of Health, and the heads of all federal entities that conduct, support, or have an interest in life sciences research (including the Assistants to the President for Homeland Security and Counterterrorism and for Science and Technology). The final NSABB recommendations and the outcomes of the NRC conference will inform the development and adoption of a new U.S. Government policy governing the funding and conduct of gain-of-function research. Upon adoption of a federal gain-of-function policy, the U.S. Government will declare the end of the research funding pause.

The life sciences community will be informed of progress at regular intervals. The estimated time-line is six months for completion of the two deliberative steps (culminating in delivery of the NSABB recommendations to the HHS Secretary) and three months for the development, approval, and publication of the policy, with the goal of completing the entire process in less than one year from declaration of the research funding pause.



U.S. Department of Health and Human Services
Framework for Guiding Funding Decisions about Proposed Research Involving Enhanced Potential Pandemic Pathogens
2017

Department of Health and Human Services Framework for Guiding Funding Decisions about Proposed Research Involving Enhanced Potential Pandemic Pathogens

Section I. Purpose and Principles

Research involving potential pandemic pathogens (PPPs) is essential to protecting global health and security. However, there are biosafety and biosecurity risks associated with undertaking such research that must be adequately considered and appropriately mitigated in order to help safely realize the potential benefits. The *HHS Framework for Guiding Funding Decisions about Proposed Research Involving Enhanced Potential Pandemic Pathogens* (*HHS P3CO Framework*) is intended to guide HHS funding decisions on individual proposed research that is reasonably anticipated to create, transfer, or use enhanced PPPs. This *HHS P3CO Framework* is responsive to and in accordance with the *Recommended Policy Guidance for Departmental Development of Review Mechanisms for Potential Pandemic Pathogen Care and Oversight* issued by OSTP on January 9, 2017[1] and supersedes the previous *Framework for Guiding Department of Health and Human Services Funding Decisions about Research Proposals with the Potential for Generating Highly Pathogenic Avian Influenza H5N1 Viruses that are Transmissible among Mammals by Respiratory Droplets*[2]. The *HHS P3CO Framework* ensures a multidisciplinary, department-level pre-funding review and evaluation of proposed research meeting the scope outlined herein to help inform funding agency decisions. In so doing, the *HHS P3CO Framework* seeks to preserve the benefits of life sciences research involving enhanced PPPs while minimizing potential biosafety and biosecurity risks.

Section II. Scope and Definitions

For the purposes of this *HHS P3CO Framework*:

A. A ***potential pandemic pathogen*** **(PPP)** is a pathogen that satisfies **both** of the following:

   1. It is likely highly transmissible and likely capable of wide and uncontrollable spread in human populations; and

   2. It is likely highly virulent and likely to cause significant morbidity and/or mortality in humans.

B. An **enhanced PPP** is defined as a PPP resulting from the enhancement of the transmissibility and/or virulence of a pathogen. Enhanced PPPs do not include naturally occurring pathogens that are circulating in or have been recovered from nature, regardless of their pandemic potential.

[1] Recommended Policy Guidance for Departmental Development of Review Mechanisms for Potential Pandemic Pathogen Care and Oversight. U.S. Government, January 2017.

[2] Framework for Guiding Department of Health and Human Services Funding Decisions about Research Proposals with the Potential for Generating Highly Pathogenic Avian Influenza H5N1 Viruses that are Transmissible among Mammals by Respiratory Droplets. U.S. Government, February 2013.

C. To the extent that transmissibility and/or virulence of PPPs are modified in the following categories of studies, the resulting pathogens are not considered to be enhanced PPPs for the purposes of this Framework[3]:

   1. Surveillance activities, including sampling and sequencing; and
   2. Activities associated with developing and producing vaccines, such as generation of high growth strains.

D. Proposed intramural and extramural life sciences research that is being considered for funding and that has been determined by the funding agency as reasonably anticipated to create, transfer, or use enhanced PPPs is subject to additional HHS department-level review as outlined herein.

E. A pathogen previously considered by an agency to be an enhanced PPP should no longer be so considered if the HHS and the White House Office of Science and Technology Policy, in consultation with the Departments of Defense, Homeland Security, Agriculture, and Justice, generally acting through the Federal Bureau of Investigation, jointly determine, on the basis of additional information that has been developed about the risks or the benefits of that pathogen's creation, transfer, or use, that the department-level review processes outlined in this framework are no longer appropriate.

[3] For additional guidance and examples of activities that would and would not be considered to involve enhanced PPP see *Recommendations for the Evaluation and Oversight of Proposed Gain-of-Function Research*. National Science Advisory Board for Biosecurity, May 2016.

Box 1. Criteria for guiding HHS funding decisions on proposed research that involves, or is reasonably anticipated to involve, creation, transfer, or use of enhanced PPPs.

Department-level review of proposed research reasonably anticipated to create, transfer, or use enhanced PPPs will be based on the following criteria:

1) The research has been evaluated by an independent expert review process (whether internal or external) and has been determined to be scientifically sound;
2) The pathogen that is anticipated to be created, transferred, or used by the research must be reasonably judged to be a credible source of a potential future human pandemic;
3) An assessment of the overall potential risks and benefits associated with the research determines that the potential risks as compared to the potential benefits to society are justified;
4) There are no feasible, equally efficacious alternative methods to address the same question in a manner that poses less risk than does the proposed approach;
5) The investigator and the institution where the research would be carried out have the demonstrated capacity and commitment to conduct it safely and securely, and have the ability to respond rapidly, mitigate potential risks and take corrective actions in response to laboratory accidents, lapses in protocol and procedures, and potential security breaches;
6) The research's results are anticipated to be responsibly communicated, in compliance with applicable laws, regulations, and policies, and any terms and conditions of funding, in order to realize their potential benefit;
7) The research will be supported through funding mechanisms that allow for appropriate management of risks and ongoing Federal and institutional oversight of all aspects of the research throughout the course of the research; and
8) The research is ethically justifiable. Non-maleficence, beneficence, justice, respect for persons, scientific freedom, and responsible stewardship are among the ethical values that should be considered by a multidisciplinary review process in making decisions about whether to fund research involving PPPs.

Section III. Review and Oversight Framework

A. The identification, review, and oversight of research subject to department-level review will require responsibilities (Figure 1) of the:

- Funding agency considering funding the proposed research; and
- HHS.

Figure 1: Overview of Responsibilities under the HHS P3CO Framework

Entity	Responsibilities
Funding agency	• Conduct standard scientific merit review; • Refer proposed research that is reasonably anticipated to create, transfer, or use enhanced PPPs for departmental-level review; • Provide relevant information necessary for departmental-level review; • Participate in departmental-level review process, as requested; • Consider the recommendations resulting from the departmental-level review; • Make a funding decision, stipulating terms and conditions of award including additional risk mitigation measures if appropriate; • Report relevant information on funding decisions to HHS and OSTP; • Ensure implementation of and adherence to required risk mitigation procedures and other terms/conditions of award, if funded.
HHS	• Convene a multidisciplinary group to review proposed research that has been determined by the funding agency as being reasonably anticipated to create, transfer, or use enhanced PPPs; • Critically evaluate the proposed research including the risk/benefit assessment and proposed risk mitigation plan; • Consider the eight criteria for guiding HHS funding decisions (Box 1) and additional relevant factors and information; • Develop recommendations on acceptability for HHS funding, including suggestions for additional risk mitigation measures and/or terms and conditions of award, if funded.

B. The HHS department-level review will evaluate proposed research referred by the funding agency that meets the scope outlined in Section II. This review and evaluation will be guided by the criteria listed in Box 1. The evaluation will include consideration of a:

- Risk/benefit analysis of the proposed research;
- Risk mitigation plan; and
- Additional relevant factors.

C. A department-level review will result in recommendations to the funding agency on whether the proposed research is acceptable for HHS funding and what, if any, additional risk mitigation measures should be incorporated into the terms and conditions of award, if funded.

D. If funded, research that is reasonably anticipated to create, transfer, or use an enhanced PPP may require additional risk mitigation strategies which may include, but are not limited to:

- Modification of the design or conduct of the research;
- Application of specific or enhanced biosecurity or biosafety and biocontainment measures;

- Evaluation of existing evidence of medical countermeasures (MCM) efficacy, or experiments conducted to determine MCM efficacy against agents or toxins resulting from the research; and
- Methodologies for responsible communication of results.

Section IV. HHS Department-level Review

A. Proposed research that is being considered for funding by the HHS funding agency, is deemed to be scientifically meritorious by an independent internal or external review process, and has been determined by the funding agency to be reasonably anticipated to create, transfer, or use enhanced PPPs must be referred for HHS department-level review.

B. The purpose of the department-level review is to provide a multidisciplinary, pre-funding review and evaluation of proposed research that meets the scope outlined in Section II to recommend whether HHS funding is appropriate, and if so, to help identify the appropriate risk mitigation strategies. The following disciplines should be represented during the department-level review: scientific research, biosafety, biosecurity, MCM development and availability, law, ethics, public health preparedness and response, biodefense, select agent regulations, and public health policy, as well as the funding agency perspectives and other relevant areas. The HHS department-level review group may include non-voting *ex officio* and/or *ad hoc* members from HHS and other federal departments and agencies as deemed appropriate by the Review Group Chair.

C. Extra care in the department-level review should be given to proposed research that is reasonably anticipated to:

- Enhance the harmful consequences of the pathogen;
- Disrupt immunity or the effectiveness of an immunization against the pathogen without clinical or agricultural justification;
- Confer to the pathogen resistance to clinically or agriculturally useful prophylactic or therapeutic interventions against that pathogen or facilitate the pathogen's ability to evade detection methodologies;
- Increase the stability, transmissibility, or the ability to disseminate the pathogen;
- Alter the host range or tropism of the pathogen;
- Enhance the susceptibility of a host population to the pathogen; or
- Generate or reconstitute an eradicated or extinct pathogen.

D. The HHS department-level review may result in the following recommendations:

- Research is acceptable for HHS funding;
- Research is not acceptable for HHS funding;
- Research is acceptable for HHS funding on the condition that certain experiments are modified;

- Research is acceptable for HHS funding on the condition that certain risk mitigation measures are employed at the federal and/or institutional level; or
- Other recommendations, as deemed appropriate.

For research determined to be not in accordance with all of the criteria for guiding HHS funding decisions on proposed research reasonably anticipated to create, transfer, or use enhanced PPPs, a recommendation will be that the research is not acceptable for HHS funding.

Section V. Evaluation of the HHS P3CO Review Process

HHS will periodically re-evaluate and modify this review process, as necessary, to reflect scientific advances and changes to the regulatory landscape. To help inform such evaluations, and to enhance transparency and public engagement in the review and oversight process for enhanced PPP research, HHS will periodically ask the National Science Advisory Board for Biosecurity to review the process described herein.

Written remarks to accompany the testimony of Steven Quay, MD, PhD

"Revisiting Gain of Function Research: What the Pandemic Taught Us and Where Do We Go From Here"
Senate Committee on Homeland Security and Governmental Affairs'
Subcommittee on Emerging Threats and Spending Oversight

Subcommittee Chair Senator Margaret Wood Hassan, Ranking Member Senator Rand Paul, Members of the Governmental Affairs' Subcommittee on Emerging Threats and Spending Oversight, invited Senator committee participants, Ladies and Gentlemen.

I am honored to participate with my esteemed colleagues, Drs. Ebright and Esvelt, in this forum entitled: "Revisiting Gain of Function Research: What the Pandemic Taught Us and Where Do We Go From Here."

My prepared remarks will take about seven minutes. I will cover six topics:

- I will begin with an overview of the evidence related to the origin of the pandemic. My conclusion from two years of investigation is that the pandemic began with a laboratory-acquired infection.
- The virus has three genomic regions that have the signature of synthetic biology, that is, gain-of-function research.
- Two of those regions involve the three types of academic gain-of-function research that are permitted.
- One region has features of the two types of forbidden gain-of-function research that are associated with bioweapons development, asymptomatic transmission and immune system evasion.
- Finally, I will present evidence of synthetic biology research at the Wuhan Institute of Virology being conducted in low level, BSL 2/3 facilities, in December 2019 on the Nipah virus, which is >60% lethal but is not naturally airborne. This is the most dangerous research I have ever encountered.
- I will close with five recommendations for future gain-of-function research.

Where did the pandemic begin?

The competing hypotheses are a natural spillover at the Huanan Seafood market in Wuhan China and a laboratory-acquired infection, most likely at the Wuhan Institute of Virology or WIV. Before December 2019, the WIV had published over 65% of all coronavirus scientific papers in the world. Until it was removed from the WIV website at 2 am local time, September 19, 2019, they maintained a database of over 21,000 viruses collected over two decades, in part with NIH funding. To my knowledge, no western scientist or organization has had access to this database since the pandemic began.

Two papers published last week by western scientists and a flurry of coordinated news coverage purported to end the debate, stating the pandemic began in the market in December 2019 and even claiming the market contained infected animals. There are at least six problems with these papers:

- No animal has ever been found to be infected with CoV-2. Hundreds from the market were tested and over 80,000 throughout China were all negative.

- All environmental specimens from the market were the result of human infection, not animal infection. For comparison, with the 2003 SARS infection >90% of market animals were infected.
- These papers suppress cases from the eastern side on the Yangtze River, near the WIV, for no apparent reason. These include cases identified during the World Health Organization investigation.
- Scientists agree that the most ancestral version of CoV-2 that infected humans, named Lineage A, did not infect any patient from the market.
- Orthogonal methods agree that the virus was circulating in Wuhan in the fall of 2019 and well before the market cases. I, as well as many others, believe the market cases were a super-spreader event.

My own research has identified the earliest cluster of hospitalized patients with both the Lineage A and Lineage B virus at the People's Liberation Army Hospital in Wuhan, identified on the chart shown here. This hospital is about 3 km from the WIV and along Line 2 of the Wuhan subway system. My research also showed that all early cases were along this same subway line, one of nine in Wuhan, and that the probability this was by chance is one in 68,000. The Line 2 COVID Conduit, as I called it, includes the PLA Hospital, the WIV, the market, and at the last stop, the international airport. You can literally walk down into the subway system and next exit in the world in London, Paris, Dubai, and New York City, all before having any symptoms. In the fall of 2019 one million people a day used Line 2 and modelling by others suggested the pandemic could not have occurred without the spreading impact of Line 2.

What are the gain-of-function features of SARS-CoV-2?

First, gain-of-function research is defined as making artificial changes to a microbe in a laboratory, seeing what new properties it acquires by those changes, and then often performing additional research to find vaccines or therapeutic that can stop this synthetic virus.

So create something that doesn't exist in nature and see if you can kill it.

The three kinds of gain-of-function research that have been agreed are acceptable in academic work are changing trophism, that is changing the host animal; changing infectivity (ease of transmission) and/or pathogenicity (how dangerous it is). Two kinds of gain-of function research have been agreed by scientists as off limits, as they have bioweapons features. These are making infections hard to detect and making viruses that can evade the immune system.

SARS-CoV-2 has features of all five kinds of gain-of-function research, including the off-limits work.

Host selection, infectivity, and pathogenicity in SARS-CoV-2 are governed by the two-step verification system used by coronaviruses to infect cells. Step one is the handshake between the receptor binding domain and the human ACE2 receptor on the surface of the human respiratory system. Step two is the spike protein cleavage site, in CoV-2 the so-called furin cleavage site, which puts a cut in the spike protein. At that point the virus injects its genetic material into the cell and begins the 12 hour or so process of replicating. This ends with the cell dissolving and thousands of new viruses being released.

In SARS-CoV-2, the receptor binding domain was largely perfected for human infection. Specifically, the first virus to infect humans had only 17 mutations it could make out of 4000 that would improve the ACE2 handshake. With SARS1, the first human infections were with a virus that had only 15% of the mutations needed for the epidemic.

How and where did the virus learn to infect humans?

In the SARS1 epidemic, once an antibody test was available to identify people who had been infected, stored blood samples were tested for previous, undiagnosed infections. Workers in the market had a 20% positivity while in the general population you could find about 1% of people who were infected. These people were the training ground on which SARS1 learned to infect humans and learn to support human-to-human spread.

Did we find a similar training ground in stored human specimens from Wuhan before the pandemic?

No. 36,000 blood specimens were tested, and none were positive. If SARS2 was like SARS1 we would have expected at least 360 positive stored specimens.

Where could SARS2 have learned to infect human?

Replicating a virus in human cell cultures, that is, a test tube would do it. So would passing the virus in mice genetically modified to contain human lung tissue, so-called humanized mice. And we know that a US coronavirus researcher, funded by the NIH, provided the WIV with his laboratory's humanized mice for doing this type of research.

The other SARS2 feature that contributed to infectivity and pathogenicity was the furin cleavage site. Many viruses use a host cell enzyme or scissors to cut a virus cell surface attachment protein as the last step before infectivity. And designing a virus in the laboratory that uses the enzyme furin by putting a synthetic furin cleavage site is a common go-to gain-of-function exercise. In fact, since 1992, at least 14 publications have described adding a furin cleavage site to a virus that didn't have one, including a study from the WIV. 14 out of 14 times it makes the viruses nastier.

In fact, a grant application from 2018 involving a collaboration between US and Chinese scientists proposed synthetically inserting a "human specific furin cleavage site" into a bat virus. Finding the exact furin cleavage site in SARS2 that is also found naturally in an important human lung protein, ENAC, that controls water flow into the lung, is very suspicious. And the backbone of SARS2, about 96% of the virus, is identical to several bat viruses. Interestingly, SARS2 is so adapted to the human host that it can no longer infect bat cells in culture.

The SARS2 furin cleavage site is also unusual in two ways. In the 1000 years since the SARS2-related viruses separated from the other related beta coronaviruses, there has never been a virus with a furin cleavage site. It is also unusual in that it uses a rare genetic sequence that has also never been used by these related viruses in nature. The sequence is a common genetic sequence used in the lab when gene jocks juice up viruses.

The furin cleavage site in SARS2 also explains why this virus but not SARS1 can infect the brain, heart, lungs, kidneys, and other organs. This is because these organs also have the furin enzyme on their surface.

What about gain-of-function features related to asymptomatic spread and immune system evasion?

Since these two features would greatly increase the pandemic potential of a virus, governments and academic scientists have agreed not to conduct gain-of-function research in these areas.

Where does SARS2 come in?

SARS2 contains a protein called ORF8, so named because it is the eighth protein in the SARS2 genome. It is one of the only proteins that is not part of the finished virus or is involved in taking over the cellular machinery that makes new viruses. ORF8 is diabolical. It is made early after an infection before other viral proteins begin to be synthesized. At this point the cell is largely unaware it is infected and hasn't mounted any defenses. ORF8 enters the blood stream and interacts with the immune system, doing two things.

First, it blocks the production of interferon. Interferon has two important functions:

First, it is a blunt weapon against infections that is used early by the body to slow down an infection, allowing time for antibodies to be produced and T-cells to respond. And second, it produces the familiar symptoms of an infection: fever, chills, sweating, red skin. The symptoms of an infection are not directly from the microbe itself but are from the body's response to the presence of a microbe. Take interferon away and you have asymptomatic spread. I am aware of no other new respiratory virus that is asymptomatic when it first entered the human population. If you remember back to the early days of COVID, no one thought we could be missing infections because of lack of symptoms. We now know that 40% of COVID from the beginning was asymptomatic.

The other property of ORF8 is that it interferes with the immune system's process of making antibodies and teaching T-cells about the virus. This so-called MHC antigen presentation system is important for fighting infections. The AIDS virus is the poster child of viruses that become chronic infections because, among other things, it inhibits the normal immune system response. No one knew about ORF8 and these features when the vaccine target was being selected and so immunity from vaccination does not include inhibiting ORF8. Interestingly, in a natural infection your body recognizes ORF8 as a highly foreign protein and actually makes more antibodies against it than any other protein.

What does this have to do with gain-of-function research at the WIV?

Prior to 2019, the WIV had conducted extensive research on optimizing the ORF8 gene and its function and on creating a synthetic biology pathway for manipulating this protein and putting it in viruses in the laboratory. This work was found in two master theses from students at the WIV that were never translated from Mandarin nor did they ever lead to publications. They were in fact found online by a group of amateur investigators self-named DRASTIC. I have found no western virologist that was doing research on ORF8 before the pandemic.

Knowing from the beginning that SARS2 had these three genetic features, that is, an optimized receptor binding domain, the effects of the furin cleavage site on transmissibility and multi-organ affinity, and the properties of ORF8 would have significantly helped in reducing the pandemics impact for three reasons:

- Human-to-human spread was accruing from the beginning and did not have to be acquired slowly, like with SARS1. The world lost almost a month of response time while public health officials made pronouncements about lack of human-to-human spread;
- Rapid spread within the body because of the humanized furin cleavage site, beginning in the lungs but leading often to multi-organ attack, could have guided treatment to better outcomes;
- And finally, knowing that 40% of cases were asymptomatic and that vaccines might be improved by including immunizing against ORF8 could have been easily done and might have improved vaccine efficacy, as well as not missing early asymptomatic cases.

Has gain-of-function research been useful to the COVID19 response or other public health infectious disease emergencies?

In looking at the collected gain-of-function research over approximately two decades, I have found no findings that could reasonably be considered to have helped in either the COVID pandemic or other smaller epidemics. At this point we know that an mRNA vaccine can be designed within literally days of a new outbreak once the pathogen is sequenced, and large-scale manufacturing can begin soon thereafter. This capability has now been fully road tested and provides, in my opinion, the best defensive capability against future microbes.

It is also important to point out that gain-of-function research is a tiny sliver of all the research funded by NIH. Specifically, there were over 36,000 RO1 grants funded by NIH in 2020, the latest year with statistics. Of these, the self-described "gain-of-function on potential pathogens" research grants numbered only twenty-one in the latest funding year. Even expanding this by tenfold with a less stringent definition of gain-of-function would mean we are talking about less than 1% of all NIH research funding.

I cannot imagine a scenario where, but for this tiny research effort, a new pandemic occurs.

What reforms should be considered in order to assure that such research is conducted in a safe and transparent manner?

While I find no actual benefit of gain-of-function research, I believe efforts to ban it, given the vested interests of literally the entire virology community, and maybe others, is a hill too steep to climb. A proposal that I believe is achievable is the placement of all select agent research within the existing institutional review board structure used for human clinical trials. The requirement to explain the cost-benefit of a particular set of experiments to unaffiliated lay people and community members could place guardrails on the field and eliminate the most dangerous research. The argument that the research is too complex to explain to non-scientists fails when you point out that chimeric antigen receptor genetic engineering of the human immune system to fight cancer is routinely placed within the oversight of the IRB system. This research is arguably more complex than gain-of-function work. In addition, the IRB system is an international standard that is used everywhere, including in China.

My second reform is to separate the governmental oversight of this research from the funding agency. We have now documented the failure of the internal NIH system, the so-called P3CO, to provide adequate oversight. The model is atomic energy research, which is funded by the Department of Defense, but which is overseen by the Atomic Energy Commission.

My third suggestion is to place the western technology of biotechnology under export controls and monitoring. There are ways to build into these systems a forensic and law enforcement capability that could, for example, with probably cause and a court-issued warrant allow

What happens if we have these hearings, and nothing changes?

A significant part of my prepared statement is derived from the evidence that I and others have collected related to the pandemic that can be sourced from outside of the WIV. In a court of law much of this would be called circumstantial evidence. While sometimes circumstantial evidence is characterized as of inferior quality it certainly does not need to be. Murders can be solved when the weapon or even the victim cannot be found. Convictions based solely on such circumstantial evidence happen all the time. But my final statement is based on actual evidence from inside the WIV. Please show the next chart.

In December 2019 five bronchial lavage specimens were taken from patients in Wuhan and sent to the WIV for analysis. The patients had pneumonia and using a sequencing machine from a US company was used to identify SARS2. The paper that was written about these patients was quickly published the first week of February and this paper has been viewed millions of times. The WIV also published the raw data that came from the specimen as well. These samples were massively expanded, using a PCR like process, and ultimately yielded tens of millions of reads of genetic material.

We took these specimen reads and conducted a forensic analysis, making three observations:

- First, we confirmed they contained the SARS2 virus.
- Second, we identified 20 unexpected contaminants in the specimens that we suspected to be the inadvertent amplification of other research going on in the laboratory. Things not expected to be found in a human specimen like honey suckle genes or a horse virus. For 19 of the 20 unexpected contaminants, we then found published research from the previous two years, confirming that the lab had indeed been working on these unexpected genes. This also validated that our methods could detect covert research efforts.
- One contaminant was not accounted for in published papers. The chart shows this finding: a portion of the Nipah virus genome in a laboratory vector commonly used for synthetic biology.

The Nipah virus is a smaller virus than SARS2 and is much less transmissible. But it is one of the deadliest viruses, with a >60% lethality. This is 60-times deadlier than SARS2. The lab where the human specimens were processed is not the highest level biosafety lab, BSL-4, but was in the BSL-2 or -3 facility.

Why were they conducting synthetic biology research in December 2019 on the Nipah virus? I cannot speculate.

But a laboratory-acquired infection with a modified Nipah virus would make the COVID19 pandemic look like a walk in the park.

The work of this committee is critical to protecting the American people and, really, the world at large, from future manmade pandemics. Thank you for the opportunity to speak before this committee.

Senate Homeland Security and Governmental Affairs Committee
Subcommittee on Emerging Threats and Spending Oversight

Credible pandemic virus identification will trigger the immediate proliferation of agents as lethal as nuclear devices

Testimony of Professor Kevin M. Esvelt, Massachusetts Institute of Technology

Introduction

Senator Hassan, Senator Paul, and members of the subcommittee, thank you for inviting me to testify on the subject of emerging threats from pandemic virus identification and enhancement research.

A million Americans have lost their lives to COVID-19, more than have perished in combat in all of our nation's foreign wars. **A pandemic virus can demonstrably kill more people than any single operational nuclear weapon.**[1]

For 75 years, the United States has successfully kept nuclear capabilities out of the hands of terrorists. Due to recent technological advances that have made it easy to assemble viruses from synthetic DNA, pandemics now represent a considerably greater challenge for nonproliferation, not least because they are wrongly viewed as a problem for health agencies that largely lack security expertise.

The threat of pandemic proliferation is still nascent: we do not yet know of any credible examples of novel viruses likely to cause a new pandemic if released.

If numerous pandemic-capable viruses are credibly identified and their genome sequences are shared with the world – as is the goal of well-meaning programs operated by the U.S. National Institutes of Health and the U.S. Agency for International Development – individual terrorists will gain the ability to unleash more pandemics at once than would naturally occur in a century.[2]

We know of at least one historical individual who both sought to acquire weapons of mass destruction for use against civilians and possessed an educational background, technical skills, and resources that would have allowed him to assemble and release viruses had he lived today.[3] Other highly capable mass murderers, including the Unabomber and certain technically skilled gunmen, would plausibly have sought out the ability to cause pandemics had they been given the opportunity. Still others may have remained unknown to us because they lacked the capability to cause sufficient damage and consequently declined to act. These examples suggest that at least one such would-be terrorist may be active today.

As a practicing biotechnologist who specializes in harnessing evolution using viruses as tools and inventing methods of editing laboratory organisms that will controllably spread in the wild,[4] **I am reasonably confident that pandemic virus identification represents a greater near-term threat to national security than anything else in the life sciences – and a more severe proliferation threat than nuclear has ever posed.**

To help understand the framework for this conclusion, my assessment considers questions of threat magnitude, proliferation, credibility, and utility. I conclude by outlining congressional actions that can delay the identification of pandemic-capable viruses long enough for us to build adequate defenses using new technologies.

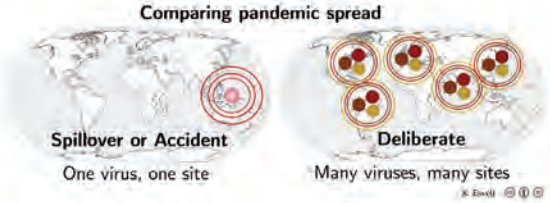
Deliberate pandemics can inflict more harm than any nuclear device or natural pandemic

SARS-CoV-2 has demonstrated that a pandemic virus spreading from a single point of origin can cause more deaths than any operational nuclear warhead, inflicting trillions in economic damages and disrupting lives worldwide. A single point of origin is the expected outcome of both natural spillovers and of lab-associated accidents, one of which was the cause of the Covid-19 pandemic in 2019.[5] At this time, the available evidence appears insufficient to determine which was responsible.

However, we can safely conclude that a deliberate pandemic involving the same virus would have been worse. A malevolent actor could have released SARS-CoV-2 in multiple travel hubs, resulting in considerably faster spread across the world and many more infections and deaths before the advent of vaccines. Indeed, unless a proven vaccine is already stockpiled in large numbers near major cities, distribution cannot plausibly inoculate people as quickly as a deliberately released virus will spread: the omicron variant spread from a single point of origin to infect 26% of Americans on the other side of the world within 100 days of detection.[6]

If many pandemic-capable viruses become known – even if each has only a moderate chance of causing a pandemic – a terrorist could assemble and release them all, potentially unleashing more and faster-spreading pandemics at the same time than would naturally occur in a century.



Successful pandemic virus identification will immediately cause widespread proliferation

Acquiring a pandemic-class agent requires 1) knowing of one or more viruses likely to cause a new pandemic, and 2) obtaining an infectious sample. Twenty years ago, the only way to obtain physical virus samples was from clinical specimens or laboratory stocks. **Today, thousands of individuals can assemble many types of viruses from commercially available synthetic DNA and virus assembly instructions**, often called "reverse genetics" protocols.

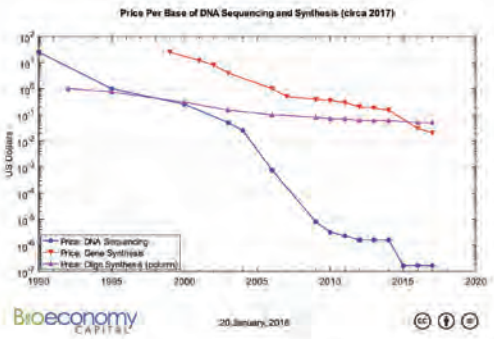
Ingredient 1: Inexpensive Synthetic DNA



In 2002, poliovirus was successfully assembled from chemically synthesized DNA.[7] Since then, the cost of synthetic genes has fallen by a factor of a thousand.

The members of the International Gene Synthesis Consortium, an industry group, have taken the lead in voluntarily screening customer orders for dangerous agents at their own expense, going well beyond the weak regulatory requirements imposed by the Department of Health and Human Services.[8] However, members comprise only an estimated 80% of the market and the membership list is publicly available.[9]

Despite the best efforts of the International Gene Synthesis Consortium, it is currently easy to obtain unscreened synthetic DNA.

Ingredient 2: Virus assembly protocols that can be performed by individuals with little tacit knowledge

Meanwhile, **virus assembly instructions have been developed for nearly all families of viruses to facilitate research on treatments**[10]. For well-studied viral subfamilies, these step-by-step protocols are so detailed that they can be successfully performed by non-specialists with basic molecular or cellular biology skills, as long as their skillset includes mammalian cell culture: the protocols are designed to remove any need for "tacit knowledge". A recently published protocol to engineer coronaviruses such as SARS-1 and SARS-2 explicitly stated that it aimed to "enable researchers from different research backgrounds to master the use of the reverse genetic system".[11]

Ingredient 3: Many individuals with the technical skills and resources needed to succeed at virus assembly

A large number of scientists, engineers, and lab technicians have the skills required to obtain many types of infectious viruses from publicly available genome sequences. Most presumably have access to laboratory facilities due to their professional work, but even if not, **a laboratory stocked with the relevant used equipment is affordable on an upper-middle-class salary in most developed nations.**

How many people can build viruses? In the U.S. alone, twenty-five new individuals receive their doctorate in the life sciences or bioengineering each day[12]; in the last 30 years, over two million people have received an equivalent degree worldwide per OECD records[13]. Even assuming that only one in ten received any training in mammalian cell culture – which is especially common among biomedical researchers – and that just one in twenty of the remainder are skilled and well-practiced enough to successfully follow a virus assembly protocol, over 10,000 people with doctorates can generate many known viruses from families for which a relevant assembly protocol is available. The number of research technicians and students may be comparable.

Another way to estimate the number is to consider how many PhDs are granted in virology, as the vast majority of such individuals must be presumed capable of following a reverse genetics protocol. The U.S. grants 125 doctoral degrees in virology each year, accounting for one-third of the total worldwide. At least four times as many individuals with degrees in related fields – such as my own PhD in biochemistry – possess similar skills. If we assume a 20-year active career, **approximately 30,000 individuals are capable of assembling any influenza virus for which a genome sequence is publicly available**.

These skills are vital to the bioeconomy, which in turn is becoming essential to human health, industrial production, environmental protection, and the continued development of a flourishing and sustainable society. The number of individuals capable of single-handedly assembling viruses from synthetic DNA will continue to grow.

Ingredient 4 (missing): Credible knowledge of novel viruses that could likely cause a new pandemic

Readily available synthetic DNA, step-by-step virus assembly protocols, and thousands of technically skilled individuals add up to many individuals who can assemble viruses, but that doesn't mean we know of any likely to cause a new pandemic. Pandemic proliferation is a nascent threat that will not be realized until someone credibly identifies a novel virus that would likely spread on its own and shares the complete genome sequence.

Consider an analogy: **we live in the biological version of a world in which weapons-grade plutonium can be mail-ordered and thousands of engineers have the skills to assemble a nuclear device, but no one knows exactly which design would work**. In that alternate reality, it's hard to imagine anyone openly seeking to identify such designs and share them online. But if cities were randomly destroyed by naturally occurring nuclear explosions, no one had ever died from a deliberate detonation, and scientists suspected that understanding how it happens might help prevent some of those natural casualties, perhaps they would. Key questions include whether doing so would be worth the cost, and how it can be done.

[13] OECD, "OECD: Graduates by Field."

How can we learn whether a virus would likely cause a pandemic if exposed to humans?

Malevolent actors interested in pandemic-capable viruses as a "poor man's nuke" will not bother trying to assemble one unless they are at least moderately confident that it would cause a pandemic. An estimated 10,000 to 320,000 mammalian viruses are thought capable of infecting humans.[14] But infection alone isn't enough: **only a tiny fraction of human-infecting animal viruses – certainly no more than a few thousand – might be transmissible enough to cause a pandemic**. By default, we can safely assume that most viruses are not pandemic-capable, even if they have been flagged by computational tools or mutated by researchers in the lab to increase transmissibility. For now, the only way to substantially increase our confidence that a given virus would cause a new pandemic is to perform a certain set of laboratory experiments.

Here is the logic: viruses currently circulating in humans are very good at infecting us and making our bodies churn out more viruses. But because most of us have already been infected and acquired some immunity, they mostly spread to children who have not been exposed or to people with weak immune systems. Pandemics happen when a new virus that can be readily transmitted jumps from animals to people: no one has much immunity, so each person infects more than one other on average, causing it to spread like wildfire. Once most people have encountered the new virus and developed resistance, it behaves like its human-adapted relatives: the average infected person passes on the virus exactly once.

This means that **any virus that is immunologically new to human populations and can efficiently infect our cells, replicate in our cells, and/or be transmitted between animals chosen for their similarity to humans nearly as well as a long-circulating human virus from the same family is reasonably likely to cause a pandemic**. Even if it is subpar at one or two of these, it only needs to be good enough to keep going long enough for a variant to arise with a mutation that makes it better – just as the original SARS-CoV-2 was outcompeted by subsequent more infectious and/or immune-evasive variants. In a deliberate large-scale release, such evolution would become more likely.

Scientists attempting to identify pandemic-capable respiratory viruses typically perform experiments measuring their ability to infect and replicate in primary human airway epithelial cells and to be transmitted between human-relevant animal models, such as engineered mice, ferrets, or primates. With NIH and USAID support, scientists from EcoHealth Alliance and the Wuhan Institute of Virology with performed these types of experiments on bat coronaviruses newly collected by virus hunters to learn whether they might cause new pandemics, and also on synthetic viruses created by mixing and matching those that seemed risky in order to learn whether such recombination might produce a pandemic-capable virus.[15] Researchers working to enhance the transmissibility of especially lethal animal viruses, like the bird flu strains engineered to be transmitted more efficiently between ferrets with NIH funding, also conduct these experiments to see whether mutated versions of these viruses may have acquired the ability to cause a pandemic.[16] **These pandemic virus identification experiments are the virological equivalent of nuclear testing**. As yet, none of them have succeeded in producing any credible threats.

Key experiments that can increase our confidence that a novel animal virus is pandemic-capable
1. Quantify the growth of the novel virus in relevant human primary cells (e.g. respiratory epithelial) 2. Quantify transmissibility in a human-relevant animal model (e.g. transgenic mice or ferrets)

Will pandemic virus identification save or cost lives?

Natural pandemics killed over a million people in 1889-91, 1918-20, 1957-59, 1968-70, and 2019-21. Might the alleged benefits of pandemic virus identification outweigh the expected harms of accident risks? What of the risks of deliberate misuse?

The issue of whether we should identify pandemic-capable viruses is entirely distinct from the controversy over the origin of SARS-CoV-2. Groups promoting and performing pandemic identification virus identification research – such as EcoHealth Alliance, the Wuhan Institute of Virology, and the Global Virome Project – believe that identifying a risky virus before the first cases appear will help prevent spillover by limiting human-animal contact and blocking transmission, and hope that it might also accelerate vaccine development. But many of the most vocal proponents of a natural origin for SARS-CoV-2 have vociferously argued that it will do neither.[17] These scientists fully support the other aspects of the One Health program for spillover prevention that are backed by USAID, but they view pandemic virus identification as a wasteful diversion of resources that would be better spent monitoring high-risk populations at the animal-human interface and helping those communities contain outbreaks.

To understand whether pandemic virus identification is worth the risk, we need low and high estimates of the benefits from early therapeutic development and improved spillover prevention, the likelihood of accidents that lead to outbreaks and then pandemics, and the probability of deliberate pandemics caused by terrorists who release one or many candidate viruses across multiple sites.

Pandemic virus identification will not significantly accelerate vaccine development. Moderna's SARS-CoV-2 vaccine was designed in less than two days. With suitable manufacturing facilities, we can produce enough doses in a week to run combined Phase I and II trials using ring vaccination to simultaneously maximize the chance of containment and learn whether our vaccine is effective. Early identification will not accelerate this timeline because we cannot run Phase II challenge trials of candidate vaccines in advance: doing so would require us to deliberately infect people with presumed pandemic-capable viruses of unknown lethality that have never infected a human and may never do so. Moreover, there are so many viruses in nature that the odds are strongly against identifying the one that will actually cause the next natural pandemic. With such a low expected rate of return, we are extremely unlikely to fund the development of such vaccines in the first place.[18] Broad-spectrum vaccines are different: they could be stockpiled in advance, but do not require us to know anything about which viruses could cause pandemics – after all, the entire point is to develop vaccines that work against an entire family of viruses – so their development will not benefit from pandemic virus identification.

[17] Holmes, Rambaut, and Andersen, "Pandemics: Spend on Surveillance, Not Prediction"; Wille, Geoghegan, and Holmes, "How Accurately Can We Assess Zoonotic Risk?".
[18] Holmes, Rambaut, and Andersen, "Pandemics: Spend on Surveillance, Not Prediction"; Wille, Geoghegan, and Holmes, "How Accurately Can We Assess Zoonotic Risk?"

Pandemic virus identification may help prevent spillover – *if* the virus would have spilled over. Since there are many more pandemic-capable viruses in animals than there are severe pandemics in a century – likely at least 100-fold more – even perfect prevention of a successfully identified virus would on average prevent only 1/100 of a pandemic. Still, for a virus equivalent to SARS-CoV-2, that would save an expected 10,000 American lives. There is a reason that many scientists think it worth trying.

The risk of an accidental pandemic may or may not outweigh the benefits of identification. Lab accidents happen routinely, but estimates of the frequency and the likelihood that they would prove infectious enough to seed a pandemic (1-30%) vary enough that the expected number of lives to accidental pandemics could be lower or higher than the lives saved through spillover prevention.[19] Perhaps surprisingly, learning the true origin of SARS-CoV-2 would barely budge these numbers.

Deliberate pandemics are expected to kill many more people than identification could save. While the possibility of deliberate pandemics has seldom been raised, simple risk calculations are straightforward.[20] Given the known existence of capable mass-murderers such as Seiichi Endo of the apocalyptic cult Aum Shinrikyo, the Aurora shooter, and the Unabomber, all of whom had or plausibly could have obtained the skills to assemble and release a virus if they lived today[21], it would be surprising if the chance that any given identified virus will be released by a terrorist was less than 1% per year… meaning each identified virus would be released within a century. Because a virus deliberately introduced at multiple sites would spread more rapidly than if the same virus were to cause a natural pandemic, successfully identifying a new equivalent of SARS-CoV-2 and sharing its genome with the world is expected to cost well over a million American lives.

Even if identifying a pandemic-capable virus in nature allowed us to perfectly prevent that virus from causing a natural pandemic, and we could do so with zero risk of accidents, we should expect terrorists to use the same virus to kill a hundred times as many Americans as would be saved.

Will malicious actors identify viruses capable of causing new pandemics if we do not?

Judging by the history of nuclear weapons, many will argue that malevolent actors will eventually identify pandemics on their own, so it's better if the good guys do it first. That may have been true of the atom bomb, but the strategic calculus for pandemics could not be more different. **Malicious actors are exceedingly unlikely to identify pandemic-capable viruses if health agencies decline to do so.**

First, it's true that rogue nations and extremist groups could gain tremendous coercive power by possessing viruses understood to be capable of causing new pandemics. These could serve as "dead-hand" switches for autocratic regimes or as convenient sources of leverage for extremist groups making demands. But neither type of actor wants to actually release such an agent, let alone give access to ideological zealots who would use it to kill them.

[19] Klotz and Sylvester, "The Consequences of a Lab Escape of a Potential Pandemic Pathogen"; Gryphon Scientific, "Risk and Benefit Analysis of Gain of Function Research"; Dobson et al., "Ecology and Economics for Pandemic Prevention."
[20] Inglesby and Relman, "How Likely Is It That Biological Agents Will Be Used Deliberately to Cause Widespread Harm? Policymakers and Scientists Need to Take Seriously the Possibility That Potential Pandemic Pathogens Will Be Misused"; Katz et al., "Mapping Stakeholders and Policies in Response to Deliberate Biological Events"; "A Spreading Plague: Lessons and Recommendations for Responding to a Deliberate Biological Event"; Sandberg and Nelson, "Who Should We Fear More: Biohackers, Disgruntled Postdocs, or Bad Governments? A Simple Risk Chain Model of Biorisk."
[21] Levy and Smithson, "Ataxia: The Chemical and Biological Terrorism Threat and the US Response"; Wikipedia contributors, "James Holmes (mass murderer)"; Kaczynski, "The Unabomber Manifesto: Industrial Society and Its Future."

Second, whereas nuclear tests yield unmistakable seismological signatures of success or failure, experimental data indicating pandemic capability is easily fabricated. Even if a rogue state or extremist group were to threaten to release a pandemic, there is no reason to believe they have a capable virus, nor to accept the validity of any alleged experimental results they might provide. Threats from rogue actors will only be taken seriously if more trustworthy actors have independently identified the virus as likely to cause a pandemic. **Since credible pandemic virus identification would give access to every ideological terrorist intent on mass murder, it is against the strategic interests of every non-suicidal malicious actor** – but if well-meaning scientists unaware or dismissive of security identify it first, many non-state actors will presumably make threats with their newly credible nuclear-equivalent capabilities.

Third, pandemic virus identification experiments are far more difficult to perform than virus assembly. While the modern equivalent of a trained mass murderer such as Seiichi Endo could unquestionably assemble many viruses, they lack the technical capability to perform basic science research at the scale needed to find the pandemic needle in the animal virus haystack. Despite recent technological advances that have made success more likely, professional scientists funded by NIAID and USAID's PREDICT program have already spent hundreds of millions of taxpayer dollars searching for pandemic viruses without finding any truly credible threats. Therefore, **while bioterrorist zealots could assemble pandemic-capable viruses that health researchers helpfully identify for them, they could not find such viruses on their own.**

Most importantly, the security agencies of established nations can be persuaded that pandemic virus identification is not in their strategic interest. Pandemic-class agents kill indiscriminately and cannot currently be engineered to spare one's own population. Large nations that attempt to vaccinate their own populations in advance would likely be discovered by foreign intelligence agencies, and even if population-specific targeting became possible, its use by a nation-state would be so obvious as to invite mass retaliation. Therefore, **pandemic-capable viruses offer little if any strategic utility to powerful nation-states; indeed, quite the opposite.** The United States, China, and even Russia have a shared interest in joining forces to prevent rogue actors and terrorist zealots from gaining access to pandemic-capable viruses.

If the United States, which historically has been the largest backer of pandemic virus identification, halts such research and explains why, even our strategic rivals are likely to follow suit.

Regulatory reforms that could prevent proliferation

COVID-19 demonstrated that we remain profoundly vulnerable to pandemic viruses spreading outwards from a single point of introduction. There is no question that would fail to contain multiple pandemic agents simultaneously released in travel hubs. But multiple new technologies need not remain helpless.

Recommendation I – announce findings, redirect funds away from pandemic virus ID, and fix oversight

Our best current defense against pandemic weapons of mass destruction is to keep them from being developed in the first place.

- First, **Congress can publicly assess the threat and release a clear finding.** A Congressional finding that experiments capable of increasing public confidence that a particular virus could cause a pandemic threatens national and international security would prove instructive for security and health agencies as well as the State Department.

- Second, **Congress can stop funding pandemic virus identification experiments.** Existing programs, whether focused on naturally collected viruses or those generated by so-called "gain-of-function" research aiming to increase transmissibility, are primarily funded by governments, including our own. I deeply respect the researchers working on these programs, who have dedicated their lives to preventing natural pandemics. I do not expect them to have carefully considered the possibility of misuse.[22] Scientists are not incentivized to become security experts; even those with an interest are unlikely to be aware of many details relevant to proliferation, such as falling gene synthesis costs, the current efficacy of DNA synthesis screening, the obviating of tacit knowledge requirements by modern virus assembly protocols, the history of nuclear weaponry, and strategic game theory.

  USAID has already pledged to cease funding transmissibility enhancement ("gain-of-function") experiments, and may not have become aware of the security implications of identifying natural pandemic-capable viruses until late 2021. Even so, they remain the largest funder of such efforts, including a new program, "DEEP VZN", that is the direct successor of the PREDICT program that funded the pandemic virus identification research in Wuhan. Because these are offshoots of larger One Health programs focused on useful virus discovery and monitoring work at the animal-human interface,[23] there would be no need to revoke any funding or break contracts: the DEEP VZN program could simply direct funds towards early warning systems rather than laboratory pandemic virus characterization. They should also refrain from publicly sharing the entire genome sequences of newly discovered viruses, as much of the genome is not relevant to vaccine or antiviral therapeutic development. USAID's "STOP SPILLOVER" program need only announce that it will no longer maintain a list of viruses rank-ordered by perceived threat level[24] due to national security and proliferation risks. Behavioral studies and public health interventions, which are important for reducing the spillover of animal pathogens into human populations and containing them when possible, can and should continue.[25] Pandemic virus identification experiments represent considerably less than 1% of all virology; banning them would be much less of an imposition on the field than are the security measures governing nuclear physics.

  NIH has a long history of funding projects aiming to enhance the transmissibility of viruses, including but not limited to lethal pathogens such as H5N1 and MERS. Many of these projects, which have been compiled and summarized by reporters from the *Washington Post*, were not covered by the moratorium on "gain-of-function" research due to disputes over what exactly is meant by that term.[26] **Congress can resolve the confusion over definitions by blocking federal funding of pandemic virus identification experiments, defined as those that could substantially increase our confidence that a virus would cause a pandemic if repeatedly introduced.**

[25] Saylors et al., "Socializing One Health: An Innovative Strategy to Investigate Social and Behavioral Risks of Emerging Viral Threats.".
[26] Willman and Muller, "A Science in the Shadows."

Experiments that may increase our confidence that a virus is pandemic-capable
1. The comparative growth of an animal virus or chimera in relevant human primary cells 2. The comparative transmission of an animal virus in a human-relevant animal model 3. The capacity of an engineered human virus* to evade innate immunity 4. The capacity of an engineered human virus* to evade pre-existing humoral immunity 5. The capacity of an engineered human virus* to evade pre-existing cellular immunity
* This category would not include viral mutants and variants thought to already be present in nature.

- **Third, Congress can require external security oversight of life sciences research.** At present, health agencies and funding recipients are instructed to regulate themselves with respect to security issues:

  > "The Department of Health and Human Services (HHS) Framework for Guiding Funding Decisions about Proposed Research Involving Enhanced Potential Pandemic Pathogens is intended to guide HHS funding decisions…"
  >
  > "Funders of life sciences research and the institutions and scientists who receive those funds have a shared responsibility for oversight of DURC (dual use research of concern) and for promoting the responsible conduct and communication of such research."

  No funding agency or recipient can be expected to oversee itself; that is the definition of a conflict of interest. The National Science Advisory Board on Biosecurity (NSABB) consists of ostensibly independent researchers, but most are primarily funded by NIH, they are appointed by HHS, and they can be dismissed at any time. Indeed, 11 of the inaugural members who had participated in discussions over research enhancing the transmissibility of highly lethal H5N1 influenza were summarily dismissed in 2014 amidst a controversy over laboratory safety mishaps involving smallpox, influenza, and anthrax. During the vote on whether to discontinue the moratorium on "gain-of-function" research involving potential pandemic pathogens, the directors of the NIH and the NIAID, whose opinions on the matter are well-known, were allegedly present in the room.

  Congress can establish a panel of experts from security agencies to provide oversight for life sciences research funded by the U.S. government, including reviewing and approving all requests for proposals before they are released. Members should be required to recuse themselves from oversight of proposals from their own agencies.

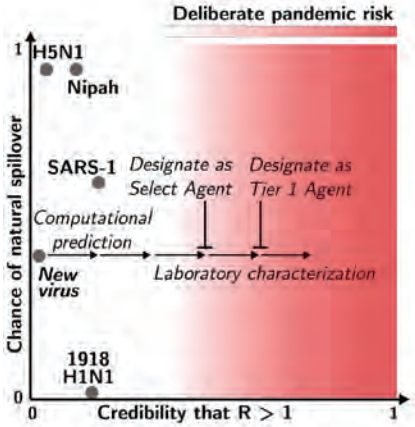
Recommendation II – Amend the 2002 Bioterrorism Response Act to update the Select Agent program

The Federal Select Agent & Toxin Program (FSAP) is unique in regulating all research in the United States, not just federally-funded entities, and additionally impacts the export control list. However, it is updated slowly, doesn't include most viruses that might be pandemic-capable, and the Act was last amended before we developed techniques such as virus chimerism, directed evolution, ancestral protein reconstruction, and machine learning approaches, all of which can plausibly generate new threats from existing ones.

Congress can update the Federal Select Agent & Toxin Program to:

1. Automatically list a virus as soon as a single result from a pandemic virus identification experiment suggests that it may be pandemic-capable[27]
2. Regulate any DNA construct that was generated from pieces of regulated Select Agents
3. Give the program the power to immediately lift all restrictions on any Select Agent confirmed to be actively spreading in order to accelerate research on countermeasures

In addition to reducing accident risks and requiring background checks of anyone working with viruses that might cause new pandemics – clearly the most hazardous of biological agents – these rules would disincentivize researchers from performing experiments to determine whether a virus they study is pandemic-capable, as doing so would automatically render it a Select Agent and increase their laboratory's cost of research several fold. As a gesture of good faith to the scientific community, FSAP might also be instructed to consider removing many listed agents that are incapable of autonomous spread and pose comparatively little risk of deliberate misuse.



Assessing pandemic risks. Pandemics may result from natural spillover, laboratory accidents, or deliberate misuse of viruses identified as credibly pandemic-capable (basic reproductive number R>1: the typical infected person infects more than one other person). Designating viruses as Select Agents upon obtaining the first experimental evidence indicative of pandemic potential could preserve the hypothesized benefits of virus discovery for "universal" virus family vaccine and broad-spectrum antiviral development while reducing accident risks and deterring characterization experiments that would otherwise result in the proliferation of viruses with presumed nuclear-equivalent lethality.

[27] **Defining pandemic-capable:** Any virus that normally circulates in a population (R~1) will cause a pandemic when introduced into a more susceptible population that lacks pre-existing immunity (R>1). This is why pandemics typically arise from viruses that spill over from other species, which spread rapidly before becoming endemic. Therefore, a virus is a credible pandemic threat if it:

- Can grow in relevant human tissues or be transmitted between relevant animal models nearly as well an endemic human virus of the same family
- Is poorly recognized by the immune systems of most humans relative to endemic human viruses of the same family

Recommendation III – leverage shared strategic interests to prevent pandemic proliferation globally

The nature of many emerging technologies places the U.S. and China at loggerheads, but our strategic interests are nearly perfectly aligned when it comes to the proliferation of access to pandemic viruses: both nations have little to gain and much to lose. This is an opportunity for the United States to gain leverage by offering information exchange and inviting co-leadership in global health security, and may help build diplomatic channels to address more challenging issues around other key technologies.

One way to marshal global action against pandemic virus prediction would utilize the Biological Weapons Convention (BWC), which prohibits the "development, stockpiling, acquisition, retention and production of biological agents" while "permitting the fullest possible exchange of equipment, materials, and information for peaceful purposes." Today, it's impossible to identify a credible pandemic-capable virus from most families, including corona-, influenza- and paramyxoviruses, without immediately giving thousands of individuals the ability to assemble infectious samples. There is a strong argument that Article III compels BWC signatories to block pandemic virus identification despite the good-intentions provisions of Article X.[28] However, the BWC is normatively important, but too general and without enforcement provisions to address pandemic proliferation. Instead, **Congress can instruct the State Department to begin negotiating a Pandemic Test-Ban Treaty that would narrowly forbid pandemic virus identification experiments, defined as those that could substantially increase our confidence that an animal virus or an engineered virus could cause a new pandemic.**

Recommendation IV – require DNA synthesis screening matching or exceeding the industry standard

Most researchers who can follow a virus assembly protocol cannot synthesize and assemble the requisite DNA or RNA, so the fact that we can order synthetic viral DNA and have it come in the mail substantially increases the number of actors capable of assembling a pandemic weapon. California's legislature passed a bill that would require all providers of synthetic DNA and manufacturers of synthesis machines to screen orders at least as well as the International Gene Synthesis Consortium, but it was vetoed on the grounds that federal legislation is needed to avoid a regulatory patchwork.[29]

A federal law requiring DNA synthesis screening would pressure domestic and international providers to screen, nudging firms to engage with the NTI/WEF stakeholder discussions on a cooperative framework and the SecureDNA project to implement new advances, including in "desktop" synthesizers, that will allow automated screening for the latest threats without having to disclose customer orders or jeopardize trade secrets.[30] Similar regulations could be encouraged internationally using the BWC or other diplomatic means.

[29] "California Legislature - AB-70 Gene Synthesis Providers."
[30] "Biosecurity Innovation and Risk Reduction: A Global Framework for Accessible, Safe and Secure DNA Synthesis"; The SecureDNA team, "Secure DNA Project - DNA Synthesis Screening."

Recommendation V – implement catastrophe liability and require insurance coverage

Despite the recently demonstrated catastrophic potential of pandemics and the controversy over accident risks, there have been surprisingly few professional risk assessments. Indeed, the United States imposed a moratorium on poorly-defined "gain-of-function" research, removed it, and replaced it with an equally poorly defined and readily evaded framework governing research on "enhanced potential pandemic pathogens" without any publication of a quantitative risk model.

Pandemic virus identification may offer great rewards – preventing 10,000 American deaths would be a major accomplishment – but there is currently no way to assess the negative externalities, let alone any market-based way to incorporate those costs into the decision-making process. With the narrow exception of nuclear policy, other actions with potentially catastrophic consequences are similarly unregulated.

Congress can encourage market-based professional risk assessment of potential catastrophes by:

1. **Passing legislation to ensure that institutions causally linked to catastrophic outcomes involving the death or disablement of a million or more Americans can be held legally liable, even for providing information permitting deliberate misuse by others, and**
2. **Requiring that general liability insurance cover such claims, up to a very large market cap chosen to prevent insurers and re-insurers from going bankrupt while providing a very strong incentive to evaluate potential sources of catastrophic risks**

The Covid-19 pandemic is the only historical event to have caused a million American deaths. World War I, World War II, HIV, the 1918 influenza pandemic, and even the Civil War did not claim so many.[51] This inherently limits the number of actions that would require review. Not only is it entirely reasonable to hold responsible anyone whose actions are subsequently shown – through the due process of law – to be instrumental in the genesis of such catastrophes, but requiring general liability insurance to cover that liability would effectively require professional risk analysts to evaluate the likelihood and set rates accordingly. That is, such a law would induce the market to impose costs upon institutions proportional to the available information concerning the likelihood that their current and planned actions will, at even very low probabilities, lead to extreme catastrophe. Requiring any findings above a minimal expected consequence (for example, probability x magnitude > 10,000 American deaths) to be made public following review and potential classification by a panel of security experts would add to society's understanding of which actions might trigger catastrophe, including by improving future assessments of the same type by insurers and prediction markets.

If a catastrophe liability and insurance act already existed, there might not be a need for Congress to determine whether to ban pandemic virus identification experiments: simply informing the insurance companies covering the institutions involved would trigger professional assessment and a corresponding increase in premiums, forcing the involved institutions to internally evaluate whether to continue with the risky behavior. If deemed worth the cost, then such actions would proceed. If not, the problem would solve itself. Either way, the negative externalities of actions with sufficiently low-probability and high-consequence outcomes would be incorporated into decision-making.

[51] Roos, "The Deadliest Events in US History."

Congressional regulation can buy time sufficient to render the U.S. able to withstand pandemics

There is a saying in cybersecurity: any system vulnerable to accidents is helpless against deliberate attack. Covid-19 may have arisen from nature or the accidental infection of a virus hunter or laboratory researcher, but it was unquestionably an accident. It follows that we are currently helpless against deliberate attacks involving pandemic-class agents. **Our current vulnerability to pandemics underscores the vital importance of ensuring that blueprints do not become publicly available.**

But if our vulnerability is extreme enough to make the situation seem hopeless, it might impede productive efforts to take action: there is a natural human inclination to freeze when confronted with a seemingly intractable problem. The deliberate release of pandemic viruses may well threaten the United States in ways that cannot be solved by medical countermeasures due to logistical constraints, no matter how quickly developed. This does not mean pandemics represent an insoluble problem. **We can immunize our country against pandemic events within a decade without any advances in biomedicine.**[32]

New algorithms are making it possible to automatically screen all DNA synthesis without revealing which sequences are considered hazardous, reducing unauthorized access to pandemic-class threats by a hundredfold and nudging scientists away from publicly disclosing them in the first place.[33] Advances in DNA sequencing will provide the United States with reliable early warning of all exponentially spreading biological threats, even those such as HIV that would not immediately show up in the clinic, for under a billion dollars a year.[34] Early warning will allow us to provide essential workers with protective equipment sufficient to enable them to do their jobs without risking their lives – an N95 mask is unlikely to suffice for a SARS-CoV-2-equivalent virus with 30% lethality, let alone something as contagious as measles, but slightly improved powered air-purifying respirators would – and enabling us to contain and eliminate threats even if groups of pandemic viruses are released in multiple airports. Personalized risk assessments provided by improved versions of contact tracing apps could tell people what fraction of their first-, second-, third-, fourth, and fifth-degree contacts have been infected, allowing only those at-risk to take precautions and dramatically reducing the cost of extinguishing small outbreaks brought in from outside our borders.[35] Perhaps most importantly, we're learning that certain wavelengths of light can kill viruses and pathogenic bacteria without even penetrating our skin or eyes; if we determine that they are as safe as preliminary studies indicate and install them in fixtures throughout the country, we could plausibly suppress a future Covid-19 or possibly even a measles-class pandemic without anyone having to wear a mask or change their routine at all… and virtually eliminate the common cold and flu while we're at it.[36]

Developing and implementing these defenses will take time. Without action by Congress, the first highly credible pandemic viruses might be publicly identified and their complete genomes irreversibly shared by well-meaning scientists funded by USAID, NIH, or other agencies as soon as this coming year. We need to keep the risk window closed for as long as possible. Disagreements over public health policy, accidents, and the origin of SARS-CoV-2 appear trivial next to this emerging technological threat to national security.

For 75 years, the United States has successfully kept nuclear capabilities out of the hands of terrorists. Today, we're on the verge of irreversibly handing them blueprints for viruses as lethal as nuclear weapons – all in the name of public health. Let's not.

This testimony reflects the personal opinions and technical expertise of Dr. Kevin M. Esvelt.
Dr. Esvelt is currently a professor at MIT, but does not speak on behalf of the Institute on this occasion.

The Honorable Rosa DeLauro
Chair
House Committee on Appropriations
U.S. House of Representatives
Washington, DC 20515

The Honorable Kay Granger
Ranking Member
House Committee on Appropriations
U.S. House of Representatives
Washington, DC 20515

The Honorable Tom Cole
Ranking Member
Subcommittee on Labor, Health and Human Services, Education
U.S. House of Representatives
Washington, DC 20515

Dear Chair DeLauro, Ranking Member Granger and Ranking Member Cole:

As Congress exercises its oversight authority over the response to the COVID-19 pandemic, we urge you to lead with science. Scientists, who have the appropriate subject-matter expertise, provide the best opportunity to answer key questions regarding the origin and transmission of the pandemic. Congress should follow an evidence-based process to ensure answers are grounded in sound science, are as complete as possible, and based in fact.

We caution against adopting policy changes absent scientific evidence, because doing so could further undermine the public's confidence in science. For future scientific progress, the implications of such proposals extend far beyond the immediate challenge of the pandemic.

We urge you to reject attempts to impose restrictions on federally funded research or the operations of federal science agencies based on premature conclusions about how the pandemic emerged. Such efforts could have serious, negative unintended consequences for potentially lifesaving research. They would harm the very ecosystem that developed the novel tests, vaccines, and medical countermeasures that have brought us through the pandemic. Continued support for research is essential for tackling a number of society's most vexing challenges, including combatting emerging infectious diseases and preventing the next pandemic.

On behalf of the scientists and clinicians our organizations and institutions represent, we urge you to allow the scientific process to play out as we seek to understand how the pandemic

began and how we can protect ourselves from future threats to our nation's health and economy.

Sincerely,

April 8, 2022

The Honorable Nancy Pelosi
Speaker
U.S. House of Representatives
Washington, DC 20515

The Honorable Kevin McCarthy
Republican Leader
U.S. House of Representatives
Washington, DC 20515

The Honorable Chuck Schumer
Majority Leader
U.S. Senate
Washington, DC 20510

The Honorable Mitch McConnell
Minority Leader
U.S. Senate
Washington, DC 20510

Dear Speaker Pelosi, Leader McCarthy, Leader Schumer and Leader McConnell:

The undersigned organizations appreciate Congress' long-standing bipartisan support for biomedical research. We also respect that oversight of research with biosafety and national security ramifications is in the best of interest of science and the nation.

As Congress negotiates far-reaching legislation focused on advancing American competitiveness through a stronger investment in federal science agencies and programs, **we urge Congress to remove legislative provisions that would restrict, pause, or alter federally funded research projects that focus on gain of function research of concern or specific pathogens.** Such an approach through legislation is overly proscriptive and interferes with the National Science Advisory Board for Biosecurity's (NSABB) evaluation of and forthcoming recommendations on enhanced potential pandemic pathogen research (EPPP) and dual use research of concern (DURC).

Established to review and advise the federal government on biosafety and biosecurity in research, including DURC and more recently, EPPP research, NSABB has the requisite scientific expertise to address these issues. Its work is essential to formulating the most effective policies for the future as we move beyond the COVID-19 pandemic and prepare for future seasonal and pandemic threats. The NSABB convened on February 28, 2022 to discuss a new, expanded charge and the path forward.

We believe it is appropriate for these polices and frameworks to be re-evaluated considering lessons learned in the current pandemic and with an eye toward both international engagement and the appropriate balance between biosecurity and the lifesaving value of this research. These efforts include the NSABB revision of definitions and consideration of pathogens classified under DURC and EPPP, and appropriately assessing research benefits with risks.

We also believe the process' inclusion of public and stakeholder input is a critical component to this evaluation because ensuring an appropriate degree of transparency in carrying out the process is important to building trust with the public and the scientific community.

Through collaboration with NSABB, Congress can strike an appropriate balance between safeguarding national security and public health through biosafety and biosecurity measures, while also recognizing the global impact of potential pandemic pathogens, the value and lifesaving potential of research in this area, and the need to study these microbes to address current and future threats. Doing otherwise could have serious, negative unintended consequences for potentially lifesaving research. They would harm the very ecosystem that developed the novel tests, vaccines, and medical countermeasures that have brought us through the pandemic.

We encourage Congress to continue exercising its oversight responsibilities and avoid legislative provisions that would pause or even halt research projects focused on specific viruses, ban specific techniques, or restrict collaboration in specific areas of the world. We thank you for your consideration of our views.

Understanding the circumstances that lead to pandemics is important for their prevention. Here, we analyze the genomic diversity of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) early in the coronavirus disease 2019 (COVID-19) pandemic. We show that SARS-CoV-2 genomic diversity before February 2020 likely comprised only two distinct viral lineages, denoted A and B. Phylodynamic rooting methods, coupled with epidemic simulations, reveal that these lineages were the result of at least two separate cross-species transmission events into humans. The first zoonotic transmission likely involved lineage B viruses around 18 November 2019 (23 October–8 December), while the separate introduction of lineage A likely occurred within weeks of this event. These findings indicate that it is unlikely that SARS-CoV-2 circulated widely in humans prior to November 2019 and define the narrow window between when SARS-CoV-2 first jumped into humans and when the first cases of COVID-19 were reported. As with other coronaviruses, SARS-CoV-2 emergence likely resulted from multiple zoonotic events.

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is responsible for the coronavirus disease 19 (COVID-19) pandemic that caused more than 5 million confirmed deaths in the two years following its detection at the Huanan Seafood Wholesale Market (hereafter the 'Huanan market') in December 2019 in Wuhan, China (*1–3*). As the original outbreak spread to other countries, the diversity of SARS-CoV-2 quickly increased and led to the emergence of multiple variants of concern, but the beginning of the pandemic was marked by two major lineages denoted 'A' and 'B' (*4*).

Lineage B has been the most common throughout the pandemic and includes all eleven sequenced genomes from humans directly associated with the Huanan market, including the earliest sampled genome, Wuhan/IPBCAMS-WH-01/2019, and the reference genome, Wuhan/Hu-1/2019 (hereafter 'Hu-1') (*5*), sampled on 24 and 26 December 2019, respectively. The earliest lineage A viruses, Wuhan/IME-WH01/2019 and Wuhan/WH04/2020, were sampled on 30 December 2019 and 5 January 2020, respectively (*6*). Lineage A differs from lineage B by two nucleotide substitutions, C8782T and T28144C, which are also found in related coronaviruses from *Rhinolophus* bats (*4*), the presumed host reservoir (*7*). Lineage B viruses have a 'C/T' pattern at these key sites (C8782, T28144), whereas lineage A viruses have a 'T/C' pattern (C8782T, T28144C). The earliest lineage A genomes from humans lack a direct epidemiological connection to the

Huanan market, but were sampled from individuals who lived or had recently stayed close to the market (*8*). It has been hypothesized that lineages A and B emerged separately (*9*), but 'C/C' and 'T/T' genomes intermediate to lineages A and B present a challenge to that hypothesis, as their existence suggests within-human evolution of one lineage toward the other via a transitional form.

Questions about these lineages remain: if lineage B viruses are more distantly related to sarbecoviruses from *Rhinolophus* bats, (i) why were lineage B viruses detected earlier than lineage A viruses and (ii) why did lineage B predominate early in the pandemic?

Answering these questions requires determining the ancestral haplotype, the genomic sequence characteristics of the most recent common ancestor (MRCA) at the root of the SARS-CoV-2 phylogeny. In this study, we combined genomic and epidemiological data from early in the COVID-19 pandemic with phylodynamic models and epidemic simulations. We eliminated many of the haplotypes previously suggested as the MRCA of SARS-CoV-2 and show that the pandemic most likely began with at least two separate zoonotic transmissions starting in November 2019.

Results

Erroneous assignment of haplotypes intermediate to lineages A and B

There are 787 near-full length genomes available from lineages A and B sampled by 14 February 2020 (data S1 and S2). However, there are also 20 genomes of intermediate haplotypes from this period containing either T28144C or C8782T but not both mutations: C/C or T/T, respectively.

We identified numerous instances of C/C and T/T genomes sharing rare mutations with lineage A or lineage B viruses, often sequenced in the same laboratory, indicating these intermediate genomes are likely artifacts of contamination or bioinformatics (*10*), similar to findings from our analysis of the emergence of SARS-CoV-2 in North America (*11*) (fig. S1 and supplementary text). We confirmed that a C/C genome from South Korea sharing three such mutations had low sequencing depth at position 28144 (≤10x), a T/T genome sampled in Singapore had low coverage at both 8782 and 28144 (≤10x), and three T/T genomes sampled in Wuhan had low sequencing depth and indeterminate nucleotide assignment at position 8782 (table S1). Further, the authors of eleven C/C genomes sampled in Wuhan and Sichuan confirmed that low sequencing depth at position 8782 led to the erroneous assignment of intermediate haplotypes.

C/C and T/T genomes continue to be observed throughout the pandemic as a result of convergent evolution, including T/T aboard the Diamond Princess cruise ship outbreak and subsequent COVID-19 waves in New York City and San Diego (fig. S2 to S5 and supplementary text). Instances of convergent evolution are identifiable because SARS-CoV-2 phylogenies exist in 'near-perfect' tree space where topology can be inferred with high accuracy (*12*). These findings cast doubt on the claim that transitional C/C or T/T haplotypes between lineages A and B circulated in humans, reopening the door to the hypothesis that lineages A and B represent separate zoonotic introductions.

Progenitor genome reconstruction

To better understand SARS-CoV-2 mutational patterns, we reconstructed the genome of a hypothetical progenitor of SARS-CoV-2. Using maximum likelihood ancestral state reconstruction across 15 non-recombinant regions of SARS-CoV-2 and closely related sarbecovirus genomes sampled from bats and pangolins (*13*), we inferred the genome of this recombinant common ancestor ("recCA") (figs. S6 and S7 and supplementary text). The recCA differed from Hu-1 by just 381 substitutions, including C8782T and T28144C. It is more informative than an outgroup sarbecovirus because it accounts for the closest relative across all recombinant segments (figs. S8 to S14 and supplementary text) (*14*), and, as an internal node on the phylogeny, is more genetically similar to SARS-CoV-2 than any extant sarbecovirus.

Reversions across the early pandemic phylogeny

The ubiquity of SARS-CoV-2 reversions (*i.e.*, mutations from Hu-1 toward the recCA) indicates that genetic similarity to related viruses is a poor proxy for the ancestral haplotype. We observe 23 unique reversions and 631 unique substitutions (excluding reversions) across the SARS-CoV-2 phylogeny from the COVID-19 pandemic up to 14 February 2020 (Fig. 1). Substitutions were overrepresented at the 381 sites separating the recCA from Hu-1 (23/381 = 6.04%), compared with substitutions at all other sites (631/29,134 = 2.17%).

Most reversions were C-to-T mutations (19/23 = 82.6%), matching the mutational bias of SARS-CoV-2 (*15–17*). Genomes with C-to-T reversions can be found within lineage A, including C18060T (lineage A.1; *e.g.*, WA1) and C29095T (*e.g.*, 20SF012), as well as C24023T, C25000T, C4276T, and C22747T in mid-late January and February 2020. Hence, triple revertant genomes, like WA1 and 20SF012, are neither unique nor rare. We also identified a lineage A genome (Malaysia/MKAK-CL-2020-6430/2020), sampled on 4 February 2020 from a Malaysian citizen traveling from Wuhan whose only four mutations from Hu-1 are all reversions (lineage A.1+T6025C) (Fig. 1). Therefore, no highly revertant haplotype can automatically be assumed to represent the MRCA of SARS-CoV-2, especially when these reversions are most often the result of C-to-T mutations. In fact, we continue to observe these reversion patterns throughout the pandemic, including in the emergence of WHO-named variants (figs. S15 and S16).

Inferring the MRCA of SARS-CoV-2

To infer the ancestral SARS-CoV-2 haplotype, we developed a non-reversible, random-effects substitution process model in a Bayesian phylodynamic framework that simultaneously reconstructs the underlying coalescent processes and the sequence of the MRCA of the SARS-CoV-2 phylogeny. The random-effects substitution model captures the C-to-T transition and G-to-T transversion biases (fig. S17 and supplementary text). Using this model, referred to as the unconstrained rooting (fig. S18A), we inferred the ancestral haplotype of the 787 lineage A and B genomes sampled by 14 February 2020.

Our unconstrained rooting strongly favors a lineage B or C/C ancestral haplotype and shows that a lineage A ancestral haplotype is inconsistent with the molecular clock [Bayes factor (BF) = 48.1] (Table 1). Lineage B exhibits more divergence from the root of the tree than would be expected if lineage A were the ancestral virus in humans (figs. S19 and S20). The T/T ancestral haplotype was also disfavored (BF>10), likely because of the C-to-T transition bias (fig. S17). We acknowledge that the timing of the earliest sampled lineage B genomes associated with the Huanan market could bias rooting inference toward lineage B haplotypes; however, lineage A was still disfavored after excluding all market-associated genomes (BF=11.0).

Even though sequence similarity to closely related sarbecoviruses alone is insufficient to determine the SARS-CoV-2 ancestral haplotype, this similarity can inform phylodynamic inference. Rather than rely on outgroup rooting [fig. S18B and (*18*)], we developed a rooting method that assigns the recCA as the progenitor of the inferred SARS-CoV-2 MRCA (fig. S18C). As opposed to the unconstrained rooting, the recCA root favored a lineage A haplotype over lineage B, although support for C/C was unchanged (Table 1). Our results were insensitive to the method of breakpoint identification in the recCA (supplementary text).

The A.1 and A+C29095T proposed ancestral haplotypes were strongly rejected by all the phylodynamic analyses, even when rooting with recCA or bat sarbecovirus outgroups, which include both C18060T and C29095T (Table 1 and data S3). Hence, WA1-like and 20SF012-like haplotypes cannot plausibly represent the MRCA of SARS-CoV-2 as previously suggested (*19–21*): the similarity of these genomes to the recCA is due to C-to-T reversions. Haplotypes not reported in Table 1 were similarly rejected (data S3).

We inferred the tMRCA for SARS-CoV-2 to be 11 December 2019 (95% HPD: 25 November–12 December) using unconstrained rooting. It has been suggested that a phylogenetic root in lineage A would produce an older time of most recent common ancestor (tMRCA) than a lineage B rooting (*21*). Therefore, we developed an approach to assign a haplotype as the SARS-CoV-2 MRCA and inferred the tMRCA (*i.e.*, A, B, C/C, A.1 or A+C29095T) (fig. S18D). The tMRCA was consistent with the recCA-rooted and fixed ancestral haplotype analyses (table S2 and supplementary text).

We infer only three plausible ancestral haplotypes: lineage A, lineage B, and C/C. However, the inability to reconcile the molecular clock at the outset of the COVID-19 pandemic with a lineage A ancestor without information from related sarbecoviruses (*e.g.*, the recCA) requires us to question the assumption that both lineages A and B resulted from a single introduction.

Separate introductions of lineages A and B

We next sought to determine whether a single introduction from one of the plausible ancestral haplotypes (lineage A, lineage B, or C/C) is consistent with the SARS-CoV-2 phylogeny. We simulated SARS-CoV-2-like epidemics (*22, 23*) with a doubling time of 3.47 days [95% highest density interval (HDI) across simulations: 1.35–5.44] (*24–26*) to account for the rapid spread of SARS-CoV-2 before it was identified as the etiological agent of COVID-19 (figs. S21 and S22, tables S3 and S4, and supplementary text). We then simulated coalescent processes and viral genome evolution across these epidemics to determine how frequently we recapitulated the observed SARS-CoV-2 phylogeny.

Lineages A and B comprise 35.2% and 64.8% of the early SARS-CoV-2 genomes, and each lineage is characterized by a large polytomy (*i.e.*, many sampled lineages descending from a single node on the phylogenetic tree), with the base of lineages A and B being the two largest polytomies observed in the early pandemic (Fig. 1). Furthermore, large polytomies are characteristic of SARS-CoV-2 introductions into geographical regions at the start of the pandemic (e.g., fig. S23) (*11, 27–29*) and would similarly be expected to occur after a successful introduction of SARS-CoV-2 into humans. Congruently, the most common topology in our simulations is a large basal polytomy (with ≥100 descendent lineages), present in 47.5% of simulated epidemics (Fig. 2A).

In contrast, a topology corresponding to a single introduction of an ancestral C/C haplotype, characterized by two clades, each comprising ≥30% of the taxa, possessing a large polytomy at the base, and separated from the MRCA by one mutation (Fig. 2B), was only observed in 0.1% of our simulations. Further, a topology corresponding to a single introduction of an ancestral lineage A or lineage B haplotype, characterized by a large basal polytomy and a large clade, comprising between 30% and 70% of taxa, two mutations from the root with no intermediate genomes, was observed in only 0.5% of our simulations (Fig. 2C, see supplementary text for details).

Our epidemic simulations do not support a single introduction of SARS-CoV-2 giving rise to the observed phylogeny. We therefore quantified the relative support for two introductions resulting in the empirical topology. By synthesizing

posterior probabilities of inferred ancestral haplotypes, frequencies of topologies in epidemic simulations, and the expected relationships between these haplotypes and topologies, we infer strong support favoring separate introductions of lineages A and B (BF=61.6 and BF=60.0 using the recCA and unconstrained rooting, respectively; see Methods). This support is robust across shorter and longer doubling times, varying ascertainment rates, and minimum polytomy size (tables S4 and S5).

If lineages A and B arose from separate introductions, then the MRCA of SARS-CoV-2 was not in humans, and it is the tMRCAs of lineages A and B that are germane to the origins of SARS-CoV-2 (i.e, not the timing of their shared ancestor). Rooting with the recCA, we inferred the median tMRCA of lineage B to be 15 December (95% HPD: 5 December to 23 December) and the median tMRCA of lineage A to be 20 December (95% HPD: 5 December to 29 December) (Fig. 3A). The tMRCA of lineage B consistently predates the tMRCA of lineage A (Fig. 3B). These results are robust to using unconstrained rooting, fixing the ancestral haplotype, and excluding market-associated genomes (Fig. 3, A and B; table S2; and supplementary text).

Timing the introductions of lineages A and B

The primary case, the first human infected with a virus in an outbreak, could precede the tMRCA if basal lineages went extinct during cryptic transmission (*23*, *30*, *31*). The index case, the first identified case, is rarely also the primary case (*32*, *33*). We next used an extension of our previously published framework combining epidemic simulations and phylodynamic tMRCA inference [see Methods; (*23*, *30*, *31*)] to infer the timing of the lineage B and lineage A primary cases, accounting for both the index case symptom onset date and earliest documented COVID-19 hospitalization date.

The earliest unambiguous case of COVID-19, with symptom onset on 10 December and hospitalization on 16 December, was a seafood vendor at the Huanan market. Unfortunately no published genome is available for this case (*8*). Nonetheless, we can reasonably assume this individual had a lineage B virus (supplementary text), as an environmental sample (EPI_ISL_408512) from the stall this vendor operated was lineage B. The earliest lineage A genome (IME-WH01) is from a familial cluster where the earliest symptom onset is 15 December and earliest hospitalization is 25 December (*34*). Accounting for these dates and using the recCA rooting, we inferred the infection date of the lineage B primary case to be 18 November (95% HPD: 23 October to 8 December) and the infection date of the primary case of lineage A to be 25 November (95% HPD: 29 October to 14 December). The lineage B primary case predated that of lineage A in 64.6% of the posterior sample, by a median of 7 days (Fig. 3D and table S6).

Our lineage A and B primary case inference is robust to rooting on the recCA and fixing the plausible ancestral haplotype to lineage A, lineage B, or C/C, as well as different index case dates, accounting for only hospitalization dates, and varying growth rates and ascertainment rates (tables S7 to S10 and supplementary text). Therefore, our results indicate that lineage B was introduced into humans no earlier than late-October and likely in mid-November 2019, and the introduction of lineage A occurred within days to weeks of this event.

We then inferred the number of ascertained infections and hospitalizations arising from these separate introductions. We find that an earlier introduction of lineage B leads to a faster rise in lineage B-associated infections, dominating the simulated epidemics (Fig. 4) and recapitulating the predominance of lineage B observed in China in early 2020 (*35*). Similarly, simulated lineage B hospitalizations are more common than those from lineage A through January 2020 (fig. S24). We observe these patterns regardless of rooting strategy (unconstrained or recCA), ancestral haplotype (B, A, or C/C) (Fig. 4 and tables S11 and S12), and doubling time (figs. S25 to S28).

Minimal cryptic circulation of SARS-CoV-2

We do not see evidence for substantial cryptic circulation before December 2019 (Fig. 4), even if we assume a single introduction (fig. S29 and supplementary text). Our simulated epidemics have a median of three (95% HPD 1-18) cumulative infections at the tMRCA, with 99% of simulated epidemics resulting in at most 33 infections (table S13 and supplementary text). Further, it is unlikely there were any COVID-19 related hospitalizations before December (*36*), as the simulated epidemics show a median of zero (95% HPD: 0–2) hospitalizations by 1 December 2019. These results are in accordance with the lack of a single SARS-CoV-2-positive sample among tens of thousands of serology samples from healthy blood donors from September to December 2019 (*37*) and thousands of specimens obtained from influenza-like illness patients at Wuhan hospitals from October to December 2019 (*34*). Therefore, there was likely extremely low prevalence of SARS-CoV-2 in Wuhan before December 2019. Even when we simulated epidemics with a longer doubling time, resulting in an earlier timing of the primary cases (tables S8 and S10), there were still few infections prior to December 2019 (table S13).

Additional introductions

The extinction rate of our simulated epidemics (*i.e.*, simulations that did not produce self-sustaining transmission chains) indicate there were likely multiple failed introductions of SARS-CoV-2. Similar to our previous findings (*23*), 77.8% of simulated epidemics went extinct. These failed introductions produced a mean of 2.06 infections and 0.10

hospitalizations; hence, failed introductions could easily go unnoticed. If we treat each SARS-CoV-2 introduction, failed or successful, as a Bernoulli trial and simulate introductions until we see two successful introductions, we estimate that eight (95% HPD: 2–23) introductions led to the establishment of both lineage A and B in humans.

Limitations

Our analysis of the putative intermediate haplotypes suggests there remain lineage assignment errors between lineages A and B, particularly of genomes sampled in January and February of 2020, which could influence the precision of the phylogenetic topology and tMRCA inference. Importantly, we lack direct evidence of a virus closely related to SARS-CoV-2 in non-human mammals at the Huanan market or its supply chain. The genome sequence of a virus directly ancestral to SARS-CoV-2 would provide more precision regarding the timing of the introductions of SARS-CoV-2 into humans and the epidemiological dynamics prior to its discovery. Although we simulated epidemics across a range of plausible epidemiological dynamics, our models represent a timeframe prior to the ascertainment of COVID-19 cases and sequencing of SARS-CoV-2 genomes and thus prior to when these models could be empirically validated.

Discussion

The genomic diversity of SARS-CoV-2 during the early pandemic presents a paradox. Lineage A viruses are at least two mutations closer to bat coronaviruses, indicating that the ancestor of SARS-CoV-2 arose from this lineage. However, lineage B viruses predominated early in the pandemic, particularly at the Huanan market, indicating that this lineage began spreading earlier in humans. Further complicating this matter is the molecular clock of SARS-CoV-2 in humans, which rejects a single-introduction origin of the pandemic from a lineage A virus. Here, we resolve this paradox by showing that early SARS-CoV-2 genomic diversity and epidemiology is best explained by at least two separate zoonotic transmissions, in which lineage A and B progenitor viruses were both circulating in non-human mammals prior to their introduction into humans (figs. S30 and S31).

The most probable explanation for the introduction of SARS-CoV-2 into humans involves zoonotic jumps from as-yet undetermined, intermediate host animals at the Huanan market (*34*, *38*, *39*). Through late-2019 the Huanan market sold animals that are known to be susceptible to SARS-CoV-2 infection and capable of intra-species transmission (*40–42*). The presence of potential animal reservoirs, coupled with the timing of the lineage B primary case and the geographic clustering of early cases around the Huanan market (*39*), support the hypothesis that SARS-CoV-2 lineage B jumped into humans at the Huanan market in mid-November 2019.

In a related study (*39*), we show that the two earliest lineage A cases are more closely positioned geographically to the Huanan market than expected compared with other COVID-19 cases in Wuhan in early 2020, despite having no known association with the market. This geographic proximity is consistent with a separate and subsequent origin of lineage A at the Huanan market in late-November 2019. The presence of lineage A virus at the Huanan market was confirmed by Gao *et al.* (*43*) from a sample taken from discarded gloves.

The high extinction rate of SARS-CoV-2 transmission chains, observed in both our simulations and real-world data (*44*), indicates that the two zoonotic events establishing lineages A and B may have been accompanied by additional, cryptic introductions. However, such introductions could easily be missed, particularly if their subsequent transmission chains quickly went extinct or the introduced viruses had a lineage A or B haplotype. Failed introductions of intermediate haplotypes are also possible. Critically, we have no evidence of subsequent zoonotic introductions in late-December leading up to the closure of the Huanan market on 1 January 2020. By then, the susceptible host animals that had been documented at the market during the previous months were no longer found in the Huanan market (*34*).

Other coronavirus epidemics and outbreaks in humans, including SARS-CoV-1, MERS-CoV, and, most recently, porcine deltacoronavirus in Haiti, have been the result of repeated introductions from animal hosts (*45–47*). These repeated introductions were easily identifiable because human viruses in these outbreaks were more closely related to viruses sampled in the animal reservoirs than to other human viruses. However, the genomic diversity within the putative SARS-CoV-2 animal reservoir at the Huanan market was likely shallower than that seen in SARS-CoV-1 and MERS-CoV reservoirs (*45*, *46*, *48*). Hence, even though lineages A and B had nearly identical haplotypes, their MRCA likely existed in an animal reservoir. The ability to disentangle repeated introductions of SARS-CoV-2 from a shallow genetic reservoir has previously been shown in the early SARS-CoV-2 epidemic in Washington state, where two viruses, separated by two mutations, were independently introduced from, and shared an MRCA in, China (figs. S23 and S30 and supplementary text) (*11*).

Successful transmission of both lineage A and B viruses after independent zoonotic events indicates that evolutionary adaptation within humans was not needed for SARS-CoV-2 to spread (*49*). We now know that SARS-CoV-2 can readily spread after reverse-zoonosis to Syrian hamsters (*Mesocricetus auratus*), American mink (*Neovison vison*), and white-tailed deer (*Odocoileus virginianus*), indicating its host generalist capacity (*50–55*). Furthermore, once an animal virus acquires the capacity for human infection and transmission,

the only remaining barrier to spillover is contact between humans and the pathogen. Thereafter, a single zoonotic transmission event indicates the conditions necessary for spillovers have been met, which portends additional jumps. For example, there were at least two zoonotic jumps of SARS-CoV-2 into humans from pet hamsters in Hong Kong (*56*) and dozens from minks to humans on Dutch fur farms (*52*, *53*).

We show that it is highly unlikely that SARS-CoV-2 circulated widely in humans earlier than November 2019 and that there was limited cryptic spread, with, at most, dozens of SARS-CoV-2 infections in the weeks leading up to the inferred tMRCA, but likely far fewer. By late-December, when SARS-CoV-2 was identified as the etiological agent of COVID-19 (*8*), the virus had likely been introduced into humans multiple times as a result of persistent contact with a viral reservoir.

Materials and methods summary

Materials and methods described in full detail can be found in the supplementary materials.

Sequence data

We queried the GISAID database (*57*), GenBank, and National Genomics Data Center of the China National Center for Bioinformatics (CNCB), for complete high-coverage SARS-CoV-2 genomes collected by 14 February 2020, resulting in a dataset of 787 taxa belonging to lineages A and B and 20 taxa with C/C or T/T haplotypes. Genomes were aligned using MAFFT v7.453 (*58*) to the SARS-CoV-2 reference genome (Wuhan/Hu-1/2019) and 388 sites were masked at the 5′ and 3′ ends and at sites based on De Maio *et al.* (*59*). All genome accessions are available in data S1 and S2.

Progenitor genome reconstruction and reversion analysis

We reconstructed the progenitor of SARS-CoV-2, the recombinant common ancestor (the recCA). We (i) inferred a maximum likelihood tree of 31 sarbecovirus genomes (SARS-CoV-2 and 30 closely related sarbecoviruses sampled from bats and pangolins) across 15 predefined non-recombinant regions (*13*) with IQ-TREE v2.0.7 (*60*), (ii) inferred the sequence of the ancestor of SARS-CoV-2 in each tree with TreeTime v0.8.1 (*61*), and (iii) concatenated the resulting sequences. We next inferred a maximum likelihood tree of the 787 SARS-CoV-2 taxa with IQ-TREE and performed ancestral state reconstruction with TreeTime to identify substitutions that were reversions from Wuhan-Hu-1 to the recCA across the SARS-CoV-2 phylogeny.

Phylodynamic inference and epidemic simulations

We performed phylodynamic inference using BEAST v1.10.5 (*62*) with the 787-taxa dataset to infer the ancestral haplotype and the tMRCA of SARS-CoV-2 (and the tMRCAs of lineages A and B), employing a non-reversible random-effects substitution model and exploring unconstrained rooting, recCA-rooting, fixing the ancestral haplotype as a root, and outgroup rooting. SARS-CoV-2-like epidemics were simulated with FAVITES-COVID-Lite v0.0.1 (*22*, *63*) using a scale-free network of 5 million individuals and a customized extension of the SAPHIRE model (*64*), producing coalescent trees on which we simulated mutations. We calculated the Bayes factor comparing the support of two introductions of SARS-CoV-2 to one introduction by considering the posterior probabilities of the four most likely ancestral haplotypes from the phylodynamic inference (Lineage A, Lineage B, C/C, and T/T), the frequencies of the phylogenetic structures associated with introductions of these haplotypes in the epidemic simulations, and equal prior probabilities for each ancestral haplotype and one versus two introductions.

We connected the phylodynamic inference and epidemic simulations via a rejection sampling-based approach (*23*), accounting for the tMRCAs of lineages A and B and the earliest documented COVID-19 illness onset and hospitalization dates. We then inferred the timing of the introductions of lineages A and B and the infections and hospitalizations for each lineage. The proportion of epidemic simulations that went extinct (*i.e.*, no onward transmission by the end of the simulation) was used to approximate the number of SARS-CoV-2 introductions needed to result in two introductions with sustained onward transmission.

ACKNOWLEDGMENTS

We gratefully acknowledge the authors from the originating laboratories and the submitting laboratories, who generated and shared via GISAID the viral genomic sequences and metadata on which this research is based (data S1) (57). We are greatly appreciative toward Lu Chen, Di Liu, and Yi Yan for providing insight into the putative intermediate genomes and clarification regarding the relative sequencing depth at positions 8782 and 28144, Marc Éloit and Sarah Temmam for sharing their sarbecovirus dataset and recombination analysis results, and Matthew Kuehnert for general feedback. Figure S30 was created with Biorender.com. **Funding:** This project has been funded in whole or in part with Federal funds from the National Institute of Allergy and Infectious Diseases, National Institutes of Health (NIH), Department of Health and Human Services, under Contract No. 75N93021C00015 (MW). JEP acknowledges support from the NIH (T15LM011271). NM acknowledges support from the National Science Foundation (NSF) (NSF-2028040). JIL acknowledges support from the NIH (5T32AI007244-38). JOW acknowledges support from the NIH (R01AI135992 and R01AI136056). RFG is supported by the NIH (R01AI132223, R01AI132244, U19AI142790, U54CA260581, U54HG007480, OT2HL158260), the Coalition for Epidemic Preparedness Innovation, the Wellcome Trust Foundation, Gilead Sciences, and the European and Developing Countries Clinical Trials Partnership Programme. MAS and AR acknowledge the support of the Wellcome Trust (Collaborators Award 206298/Z/17/Z – ARTIC network), the European Research Council (grant agreement no. 725422 – ReservoirDOCS) and the NIH (R01AI153044). KGA is supported by the NIH (U19AI135995, U01AI151812, and UL1TR002550). ECH is funded by an Australian Research Council Laureate Fellowship (FL170100022). JIL, HP, and MSP acknowledge support from the National Research Foundation of Korea, funded by the Ministry of Science and Information and Communication Technologies, Republic of Korea (NRF-2017M3A9E4061995 and NRF-2019R1A2C2084206). TIV acknowledges support from the Branco Weiss Fellowship. We thank AMD for the donation of critical hardware and support resources from its HPC Fund that made this work possible. This work was supported (in part) by the Epidemiology and Laboratory Capacity (ELC) for Infectious Diseases Cooperative Agreement (Grant Number: ELC DETECT (6NU50CK000517-01-07) funded by the Centers for Disease Control and Prevention (CDC). Its contents are solely the responsibility of the authors and do not necessarily represent the official views of CDC or the Department of Health and Human Services. **Author contributions:** Conceptualization: JEP, MAS, KGA, MW, JOW; Methodology: JEP, AM, NM, MAS, KGA, MW, JOW; Software: JEP, AM, NM, KG, MAS; Validation: JEP, AM, KI, KG, MAS; Formal analysis: JEP, AM, EP, KI, JLH, KG, JOW; Investigation: JEP, AM, EP, KI, JLH, KG, JOW; Resources: MAS, KGA, JOW; Data Curation: JEP, EP, KG, MZ, JCW, SH, JL, HP, MP, KCZY, RTPL, MNMI, YMN, JOW, Writing - original draft preparation: JEP, MW, JOW; Writing - review and editing: All Authors; Visualization: JEP, JLH, KG, LMMS; Supervision: MAS, KGA, MW, JOW; Project administration: MAS, KGA, MW, JOW; Funding acquisition: MAS, KGA, MW, JOW. **Competing interests:** JOW has received funding from the CDC (ongoing) via contracts or agreements to his institution unrelated to this research. MAS receives contracts and grants from the US Food and Drug Administration, the US Department of Veterans Affairs and Janssen Research and Development unrelated to this research. RFG is co-founder of Zalgen Labs, a biotechnology company developing countermeasures to emerging viruses. MW, ECH, AR, MAS, JOW, and KGA have received consulting fees and/or provided compensated expert testimony on SARS-CoV-2 and the COVID-19 pandemic. **Data and materials availability:** Genome accessions are available in data S1 and S2, and raw data for two genomes were deposited to NCBI SRA (PRJNA806767 and PRJNA802993). Code is available on Zenodo (65). The following data are available on Data Dryad (66): recCA sequence, BEAST phylogenetic inference output, and simulation and rejection sampling output for the primary analysis.

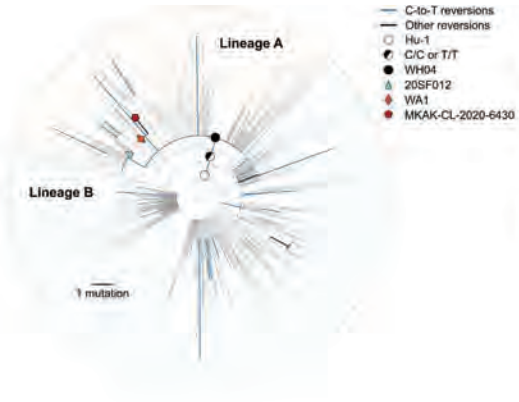

Fig. 1. Maximum likelihood phylogeny of the early SARS-CoV-2 pandemic, showing nucleotide reversions and putative candidates for the ancestral haplotype at the most common recent ancestor (MRCA). Putative ancestral haplotypes are identified with colored shapes. Reversions from the Hu-1 reference genotype to the recCA are colored. Blue represents C-to-T reversions and black indicates all other reversions. The tree is rooted on Hu-1 to show reversion dynamics to the recCA.

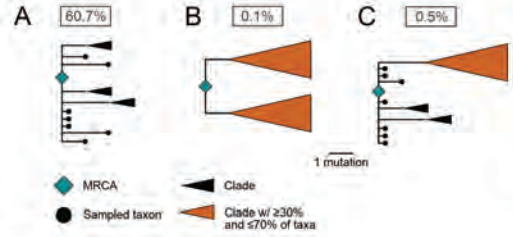

Fig. 2. Probability of phylogenetic structures arising from a single introduction of SARS-CoV-2 in epidemic simulations. (A) A large polytomy of at least 20 descendent lineages, consistent with the base of both lineages A and B. (B) Topology matching a C/C ancestral haplotype: two clades each one mutation from the ancestor, both with polytomies of at least 20 descendent lineages. (C) Topology matching either a lineage A or lineage B ancestral haplotype: a basal polytomy with at least 20 descendent lineages including a large clade separated by two mutations, also possessing a polytomy of at least 20 descendent lineages. Basal taxa have short branch lengths for clarity. The probability of each phylogenetic structure after a single introduction is reported in the box.

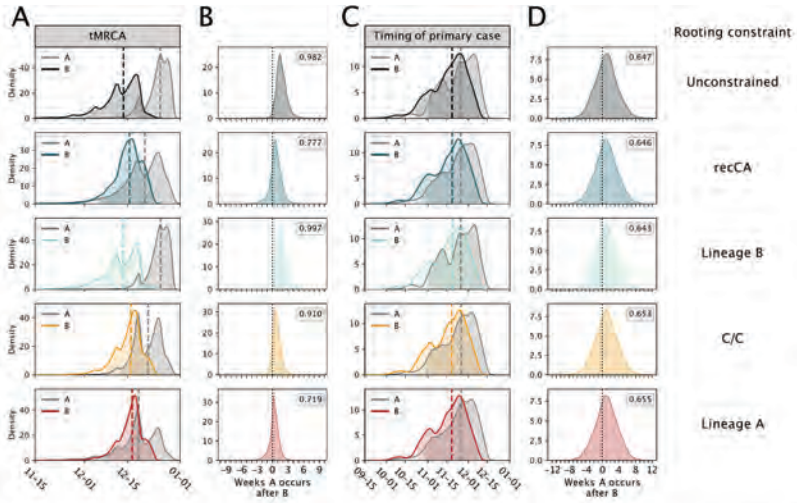

Fig. 3. Comparison of the tMRCA and primary case dates for lineage A and lineage B across rooting strategies. Each row represents a different rooting constraint in phylodynamic analysis. with lineage B, C/C and lineage A representing a fixed ancestral haplotype. (**A**) The tMRCA for lineages A and B. (**B**) The number of weeks the tMRCA of lineage A occurs after the tMRCA of lineage B. (**C**) The timing of the primary case for lineages A and B. (**D**) The number of weeks the time of the primary case of lineage A occurs after the time of the primary case of lineage B. Long dashed lines indicate the median and shading represents the 95% HPD for each distribution. Short dashed lines indicate 0 weeks difference between lineages A and B. Posterior probability that lineage A originated after lineage B is reported in the grey box.

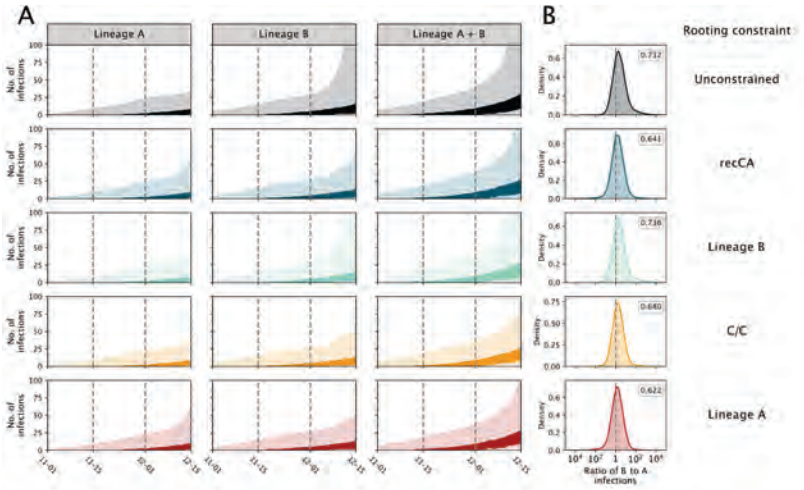

Fig. 4. Dynamics of simulated SARS-CoV-2 epidemics resulting from separate introductions of lineages A and B. Each row represents a different rooting constraint in phylodynamic analysis, with lineage B, C/C and lineage A representing a fixed ancestral haplotype. (**A**) Estimated number of infections. The header of each column indicates whether the number of infections are caused by lineage A, lineage B, or the two lineages combined. Darker and lighter shading represent the 50% and 95% HPD, respectively. (**B**) The log ratio of lineage B to lineage A infections on 15 December 2019. Posterior probability of having more lineage B infections than lineage A reported in the grey box.

Table 1. Posterior probabilities of inferred ancestral haplotype at the MRCA of SARS-CoV-2. Positions 8782 and 28144 are indicated in parentheses. Representative genome is that with its sequence matching the haplotype. "No market" excludes 15 market-associated genomes (13 lineage B genomes associated with the Huanan market plus one lineage A and one lineage B genome not associated with the Huanan market). *BF > 10. **BF > 100. ***BF > 1000; BFs are in favor of hypothesis rejection.

Understanding how severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) emerged in 2019 is critical to preventing zoonotic outbreaks before they become the next pandemic. The Huanan Seafood Wholesale Market in Wuhan, China, was identified as a likely source of cases in early reports but later this conclusion became controversial. We show the earliest known COVID-19 cases from December 2019, including those without reported direct links, were geographically centered on this market. We report that live SARS-CoV-2 susceptible mammals were sold at the market in late 2019 and, within the market, SARS-CoV-2-positive environmental samples were spatially associated with vendors selling live mammals. While there is insufficient evidence to define upstream events, and exact circumstances remain obscure, our analyses indicate that the emergence of SARS-CoV-2 occurred via the live wildlife trade in China, and show that the Huanan market was the epicenter of the COVID-19 pandemic.

On 31 December 2019, the Chinese government notified the World Health Organization (WHO) of an outbreak of severe pneumonia of unknown etiology in Wuhan, Hubei province (*1–4*), a city of approximately 11 million people. Of the initial 41 people hospitalized with unknown pneumonia by 2 January 2020, 27 (66%) had direct exposure to the Huanan Wholesale Seafood Market (hereafter, "Huanan market") (*2, 5, 6*). These first cases were confirmed to be infected with a novel coronavirus, subsequently named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and were suffering from a disease later named coronavirus disease 2019 (COVID-19). The initial diagnoses of COVID-19 were made in several hospitals independently between 18 and 29 December 2019 (*5*). These early reports were free from ascertainment bias as they were based on signs and symptoms before the Huanan market was identified as a shared risk factor (*5*). A subsequent systematic review of all cases notified to China's National Notifiable Disease Reporting System by hospitals in Wuhan as part of the joint WHO-Chinese "WHO-convened global study of origins of SARS-CoV-2: China Part" (hereafter, "WHO mission report") (*7*) showed that 55 of 168 of the earliest known COVID-19 cases were associated with this market. However, the observation that the preponderance of early cases were linked to the Huanan market does not establish that the pandemic originated there.

Sustained live mammal sales during 2019 occurred at the Huanan and three other markets in Wuhan, including wild and farmed wild-life (*8*). Several of these species are known to be experimentally susceptible to SARS-related coronaviruses (SARSr-CoVs), such as SARS-CoV (hereafter, "SARS-CoV-1") and SARS-CoV-2 (*9–11*). During the early stages of the COVID-19 pandemic, animals sold at the Huanan market

were hypothesized to be the source of the unexplained pneumonia cases (*12–19*) (data S1), consistent with the emergence of SARS-CoV-1 from 2002-2004 (*20*), as well as other viral zoonoses (*21–23*). This led to the decision to close and sanitize the Huanan market on 1 January 2020, with environmental samples also being collected from vendors' stalls (*7, 12, 24*) (data S1).

Determining the epicenter of the COVID-19 pandemic at a neighborhood- rather than city-level could help resolve if SARS-CoV-2 had a zoonotic origin, similar to SARS-CoV-1 (*20*). In this study, we obtained data from a range of sources to test the hypothesis that the COVID-19 pandemic began at the Huanan market. Despite limited testing of live wildlife sold at the market, collectively, our results provide evidence that the Huanan market was the early epicenter of the COVID-19 pandemic and suggest that SARS-CoV-2 likely emerged from the live wildlife trade in China. However, events upstream of the market, as well as exact circumstances at the market, remain obscure, highlighting the need for further studies to understand and lower the risk of future pandemics.

Results

Early cases lived near to and centered on the Huanan market

The 2021 WHO mission report identified 174 COVID-19 cases in Hubei province in December 2019 after careful examination of reported case histories (*7*). Although geographical coordinates of the residential locations of the 164 cases who lived within Wuhan were unavailable, we were able to reliably extract the latitude and longitude coordinates of 155 cases from maps in the report (figs. S1 to S8).

While early COVID-19 cases occurred across Wuhan, the majority clustered in central Wuhan near the west bank of the Yangtze River, with a high density of cases near to, and surrounding, the Huanan market (Fig. 1A). We used a kernel density estimate (KDE) to reconstruct an underlying probability density function from which the home locations for each case were drawn (*25*). Using all 155 December 2019 cases, the location of the Huanan market lies within the highest density contour that contains 1% of the probability mass (Fig. 1B). For a KDE estimated using the 120 cases with no known linkage to the market, the market remains within the highest density 1% contour (Fig. 1C). The clustering of COVID-19 cases in December around the Huanan market (Fig. 1, B and C, insets) contrasts with the pattern of widely dispersed cases across Wuhan by early January through mid-February 2020 (Fig. 1, D and E), which we mapped using location data from individuals using a COVID-19 assistance app on Sina Weibo (*26*). Weibo-based data analyses show that, unlike early COVID-19 cases, by January and February many of the sick who sought help resided in highly populated areas of the city, and particularly in areas with a high density of older people (Fig. 1E and figs. S9 and S10).

We also investigated whether the December COVID-19 cases were closer to the market than expected based on an empirical null distribution of Wuhan's population density (data from worldpop.org (*27, 28*)), with its median distance to the Huanan market of 16.11km (*25*). To account for older individuals being more likely to be hospitalized and sick with COVID-19 (*29*), we age-matched the population data to the December 2019 COVID-19 case data. We considered three categories of cases, and they were all significantly closer to the Huanan market than expected: (*i*) all cases (median 4.28km: $p<0.001$), (*ii*) cases linked directly to the Huanan market (median 5.74km; $p<0.001$), and (*iii*) cases with no evidence of a direct link to the Huanan market (median 4.00km: $p<0.001$) (Fig. 2A). The cases with no known link to the market on average resided closer to the market than the cases with links to the market ($p=0.029$). Furthermore, the distances between the center-points (Fig. 2B) and the Huanan market were shorter than expected for all categories of December cases compared with the empirical null distribution of Wuhan's population density (Fig. 2A). For all the December cases the center-point was located 1.02km away ($p=0.007$); the center-point for cases with market links was 2.28km away ($p=0.034$), and the center-point for the cases with no reported link to the market was 0.91km away ($p=0.006$). In comparison, the center-point of age-matched samples drawn from the empirical null distribution was 4.65km away from the market (Fig. 2A).

We tested the robustness of our results to the possibility of ascertainment bias (*25*). For all mapped cases ($n=155$), under the 'center-point distance to the Huanan market' test, the 38 cases residing closest to the market (within a radius of 1.6km) could be removed from the data set before losing significance at the $\alpha=0.05$ level (fig. S12). For the 'median distance to Huanan market' test, we could remove 98 (63%) ($r=5.8$km). For cases not directly linked to the Huanan market (n=120), we could remove 36 (30%) ($r=1.5$km) and 81 (68%) ($r=4.3$km) for the two tests, respectively, before losing significance at the $\alpha=0.05$ level (fig. S12).

We performed a spatial relative risk analysis (*25*) to compare December 2019 COVID-19 cases with January-February 2020 cases, reported via Weibo (Fig. 2C). The Huanan market is located within a well-defined area with high case density that would be expected to be observed in fewer than one in 100,000 samplings of the Weibo data empirical distribution (relative risk analysis in Fig. 2C, control distribution in Fig. 1D). No other regions in Wuhan showed a comparable case density.

Both early lineages of SARS-CoV-2 were geographically associated with the market

Two lineages of SARS-CoV-2 designated A and B (*30*) have co-circulated globally since early in the COVID-19 pandemic (*31*). Until a report in a recent preprint (*24*), only lineage B

sequences had been sampled at the Huanan market. The eleven lineage B cases from December 2019, for which we have location information, resided closer than expected to the Huanan market compared to the age-matched Wuhan population distribution (median 8.30km; p=0.017) (*25*). The center-point of the eleven lineage B cases was 1.95km from the Huanan market, also closer than expected (p=0.026). The two lineage A cases for which we have location information involved the two earliest lineage A genomes known to date. Neither case reported any contact to the Huanan market (*7*). The first case was detected before any knowledge of a possible association of unexplained pneumonia in Wuhan with the Huanan market (*5*) and therefore could not have been a product of ascertainment bias in favor of cases residing near the market. The second had stayed in a hotel near the market (*32*) for the five days preceding symptom onset (*25*). Relative to the age-matched Wuhan population distribution, the first individual resided closer to the Huanan market (2.31km) than expected (p=0.034). While the exact location of the hotel near the market was not reported (*32*), there are at least 20 hotels within 500 m (table S1). Under the conservative assumption that the hotel could have been located as far as 2.31km from the Huanan market (as was the residence of the other lineage A case), and assuming this location is comparable to a residential location given the timing of the stay prior to symptom onset (*25*), it would be unlikely to observe both the earliest lineage A cases this near to the Huanan market (p=0.001 or less). That both identified lineage A cases had a geographical connection to the market, in combination with the detection of lineage A within the market (*24*), support the likelihood that during the early epidemic lineage A was, like lineage B, disseminating outward from the Huanan market into the surrounding neighborhoods.

Our statistical results were robust to a range of factors, for example, the use of an empirical control distribution based on presumptive COVID-19 cases locations later in the Wuhan epidemic (Weibo data); laboratory-confirmed versus clinically-diagnosed cases; and uncertainty in case location or missing data (figs. S13 to S15) (*25*). For instance, we artificially introduced location uncertainty ('noise') in each case location in our data set by randomly re-sampling each point within a circle of radius 1000m centered on its original center-point; the conclusions were unaffected (fig. S13). The extraction method we employed actually introduced up to about 50m of noise in each case location estimate (fig. S7), ruling out the possibility that our overall results were affected by this source of error. The results were also robust when corrected for multiple hypothesis testing (table S4).

Wild animal trading in Wuhan markets

In addition to selling seafood, poultry, and other commodities, the Huanan market was among four markets in Wuhan reported to consistently sell a variety of live, wild-captured or farmed, mammal species in the years and months leading up to the COVID-19 pandemic (*8*). There are, however, no prior reports of which species, if any, were sold at the Huanan market in the months leading up to the pandemic. Here, we report that multiple plausible intermediate wildlife hosts of SARS-CoV-2 progenitor viruses, including red foxes (*Vulpes vulpes*), hog badgers (*Arctonyx albogularis*) and common raccoon dogs (*Nyctereutes procyonoides*), were sold live at the Huanan market up until at least November of 2019 (Table 1 and table S5). No reports are known to be available for SARS-CoV-2 test results from these mammals at the Huanan market. Despite a general slow-down in live animal sales during the winter months, we report that raccoon dogs that are sold for both meat and fur were consistently available for sale throughout the year, including at the Huanan market in November 2019 (Table 1 and table S5).

There were potentially many locations in Wuhan, a city of 11 million, that would have been equally or more likely than the Huanan market to sustain the first recognized cluster of a new respiratory pathogen had its introduction not been linked to a live animal market, including other shopping venues, hospitals, elder care facilities, workplaces, universities, and places of worship. To investigate possible sites, we compared the relative extent of intra-urban human traffic to the Huanan market versus other locations within the city of Wuhan using a location-specific data set of social media check-ins in the Sina Visitor System (*25, 33*). We found at least 70 other markets throughout the city of Wuhan that received more social media visitors than the Huanan market (Fig. 3). To extend this analysis beyond only markets, we also used a subsequently published list of known SARS-CoV-2 superspreader locations (*34*) to identify 430 locations in Wuhan that may have been at high risk for superspreader events and which received more check-ins than the Huanan market (Fig. 3, inset). The Huanan market accounted for 0.12% (120 of 98,146) of social media check-ins to markets in the data set that received at least as many check-ins as the Huanan market. The market accounted for 0.04% (120 of 262,233) of all social media check-ins to the >400 sites in Wuhan identified as especially likely to be potential superspreader locations and which received at least as many social media visits as the Huanan market. Considering the number of check-ins to all four markets selling live, wild animals in Wuhan (combined), they accounted for 0.21% (206 of 98,146) of market visits and 0.079% (206 of 262,233) of visits to the 430 potential superspreader sites, where a new respiratory disease might first be noticed in a large city.

A data set from the Chinese Center for Disease Prevention and Control (CCDC) report dated 22 January 2020 (data S1) (*12, 13, 15, 16*) was made publicly available in June 2020 (*24, 35*). 585 environmental samples were initially taken from various surfaces in the Huanan market on 1 and 12 January 2020 by the

CCDC (tables S6 and S7 and data S1) (*12, 13, 15, 16, 24, 35*), with further samples taken through the market during January and February (*24*). We extended the analysis in the WHO mission report (*7*) by integrating public online maps and photographic evidence, data from public business registries (table S8 and data S2), information about which live mammal species were sold at the Huanan market in late 2019 (Table 1 and table S5), and the CCDC report (data S1). We reconstructed the floor plan of the market and integrated information from business registries of vendors at the market (fig. S16 and table S8), as well as an official report (*36*) recording fines to three business owners for illegal sale of live mammals (data S2) (*36*). From this, we identified an additional five stalls that were likely selling live or freshly butchered mammals or other unspecified meat products in the southwest corner of the western section of the market (Fig. 4A, figs. S16 and S17, and table S6).

Five of the SARS-CoV-2-positive environmental samples were taken from a single stall selling live mammals in late 2019 (table S6). Further, the objects sampled showed an association with animal sales, including a metal cage, two carts (of the kind frequently used to transport mobile animal cages) and a hair/feather remover (table S6). No human COVID-19 cases were reported there (*7, 12*). The same stall was visited by one of us (ECH) in 2014, who then observed live raccoon dogs housed in a metal cage stacked on top of a cage with live birds (Fig. 4A) (*37*). A recent report (*24*) identified that the grates outside of this stall, upon which animal cages were stacked (*37*), were positive for SARS-CoV-2.

Positive environmental samples linked both to live mammal sales and to human cases at the Huanan market

We used a spatial relative risk analysis to identify potential regions of the market with an increased density of positive environmental samples (*25*). We found evidence ($p<0.05$) of a region in the southwest area of the market where live mammals were on sale (Fig. 4B). Although environmental sampling of the market was incomplete and spatially heterogeneous (data S1 and table S6), our analysis accounts for the empirical environmental sampling distribution, which was biased toward 'stalls related to December cases' as well as 'stalls that sold livestock, poultry, farmed wildlife' (*7*) (Fig. 4, C and D). The 'distance to the nearest vendor selling live mammals' and 'distance to the nearest human case' were independently predictive of environmental sample positivity ($p=0.004$ and 0.014, respectively for N=6; table S9). To further investigate the robustness of these findings to possible sampling biases, we considered three scenarios: (*i*) oversampling of live mammal and unknown meat stalls, (*ii*) overcounting of positive samples, and (*iii*) exclusion of the seafood stand near the wildlife area of the market (with five positive samples) from our analysis (table S10). In each case, the distance to live mammal vendors remained predictive of environmental sample positivity, and the region of increased positive sample density in the southwest corner of the western section of the market remained consistent (fig. S18).

Finally, to analyze the spatial patterning of human cases within the Huanan market, we plotted cases as a function of symptom onset from the WHO mission report (*7*) (Fig. 5A and table S11) (*25*). All eight COVID-19 cases detected prior to 20 December were from the western side of the market, where mammal species were also sold (Fig. 5, B and C). Unlike SARS-CoV-2 positive environmental samples (Fig. 4, A and C), we found that COVID-19 cases were more diffuse throughout the building (Fig. 5).

Study limitations

There are several limitations to our study. We have been able to recover location data for most of the December-onset COVID-19 cases identified by the WHO mission (*7*) and have been able to do so with sufficient precision to support our conclusions. However, we do not have access to the precise latitude and longitude coordinates of all these cases. Should such data exist, they may be accompanied by additional metadata, some of which we have reconstructed, but some of which, including the date of onset of each case, would be valuable for ongoing studies. We also lack direct evidence of an intermediate animal infected with a SARS-CoV-2 progenitor virus either at the Huanan market or at a location connected to its supply chain, like a farm. Additionally, no line list of early COVID-19 cases is available and we do not have complete details of environmental sampling, though compared to many other outbreaks, we have more comprehensive information on early cases, hospitalizations and environmental sampling (*7*).

Discussion

Several lines of evidence support the hypothesis that the Huanan market was the epicenter of the COVID-19 pandemic and that SARS-CoV-2 emerged from activities associated with live wildlife trade. Spatial analyses within the market show that SARS-CoV-2-positive environmental samples, including cages, carts, and freezers, were associated with activities concentrated in the southwest corner of the market. This is the same section where vendors were selling live mammals, including raccoon dogs, hog badgers, and red foxes, immediately prior to the COVID-19 pandemic. Multiple positive samples were taken from one stall known to have sold live mammals, and the water drain proximal to this stall, as well as other sewerages and a nearby wildlife stall on the southwest side of the market, tested positive for SARS-CoV-2 (*24*). These findings suggest that infected animals were present at the Huanan market at the beginning of the COVID-19

pandemic; however, we do not have access to any live animal samples from relevant species. Additional information, including sequencing data and detailed sampling strategy, would be invaluable to test this hypothesis comprehensively.

In a related study, we infer separate introductions of SARS-CoV-2 lineages A and B into humans from likely infected animals at the Huanan market (*38*). We estimate the first COVID-19 case to have occurred in November 2019, with few human cases and hospitalizations occurring through mid-December (*38*). A recent preprint (*24*) confirms the authenticity of the CCDC report (data S1) and records additional positive environmental samples in the southwestern area of the market selling live animals. This report also documents the early presence of the A lineage of SARS-CoV-2 in a Huanan market environmental sample. This, along with the lineage A cases we report in close geographical proximity to the market in December, challenges the suggestion that the market was simply a superspreading event, which would be lineage-specific. Rather, it adds to the evidence presented here that lineage A, like lineage B, may have originated at the Huanan market then spread from this epicenter into the neighborhoods surrounding the market and then beyond.

Several observations suggest that the geographic association of early COVID-19 cases with the Huanan market is unlikely to have been the result of ascertainment bias (supplementary text and tables S2 and S3) (*39*). These include: (*i*) few, if any, cases among Huanan market-unlinked individuals are likely to have been detected by active searching in the neighborhoods around the market – only in hospitals – since all cases analyzed here were hospitalized (*7*), (*ii*) public health officials simultaneously became aware of Huanan-linked cases near and far from the Huanan market, not just ones near it (fig. S11) (*5*), (*iii*) Huanan-unlinked cases would not be expected to live significantly closer to the market than linked cases if they had been ascertained as contacts traced from those market-linked cases, and (*iv*) seroprevalence in Wuhan was highest in the districts around the market (*40*, *41*). It is also noteworthy that the December 2019 COVID-19 cases we consider here were identified based on reviews of clinical signs and symptoms, not epidemiological factors such as where they resided or links to the Huanan market (*7*) and that excess deaths from pneumonia rose first in the districts surrounding the market (*42*). Moreover, the spatial relationship with the Huanan market remains after removing the two-thirds of the unlinked cases residing nearest the market.

One of the key findings of our study is that 'unlinked' early COVID-19 patients, those who neither worked at the market or knew someone who did, nor had recently visited the market, resided significantly closer to the market than patients with a direct link to the market. The observation that a substantial proportion of early cases had no known epidemiological link had previously been used as an argument against a Huanan market epicenter of the pandemic. However, this group of cases resided significantly closer to the market than those who worked there, indicating that they had been exposed to the virus at, or near, the Huanan market. For market workers, the exposure risk was their place of work not their residential locations, which were significantly further afield than those cases not formally linked to the market.

Our spatial analyses show how patterns of COVID-19 cases shifted between late 2019, when the outbreak began (*43*), and early 2020, as the epidemic spread widely across Wuhan. COVID-19 cases in December 2019 were associated with the Huanan market in a manner unrelated to Wuhan population density or demographic patterns, unlike the wide spatial distribution of cases observed during later stages of the epidemic in January and February. This observation fits with the evidence from other sources that SARS-CoV-2 was not widespread in Wuhan at the end of 2019. For example, no SARS-CoV-2-positive sera or influenza-like illness (ILI) reports were recorded among more 40,000 blood donor samples collected up to December 2019 (*44*, *45*), and none of thousands of samples taken from ILI patients at Wuhan hospitals in October-December 2019 tested for SARS-CoV-2 RNA was positive (*7*).

The sustained presence of a potential source of virus transmission into the human population in late 2019, plausibly from infected live mammals sold at the Huanan market, offers an explanation of our findings and the origins of SARS-CoV-2. The pattern of COVID-19 cases reported for the Huanan market, with the earliest cases in the same part of the market as the wildlife sales and evidence of at least two introductions (*38*), resembles the multiple cross-species transmissions of SARS-CoV-2 subsequently observed during the pandemic from animals to humans on mink farms (*46*), and from infected hamsters to humans in the pet trade (*47*). There was an extensive network of wildlife farms in western Hubei province, including hundreds of thousands of raccoon dogs on farms in Enshi prefecture, which supplied the Huanan market (*48*). This region of Hubei contains extensive cave complexes housing *Rhinolophus* bats, which carry SARSr-CoVs (*49*). SARS-CoV-1 was recovered from farmed masked palm civets from Hubei in 2003 and 2004 (*20*). The animals on these farms (nearly 1 million) were rapidly released, sold, or killed in early 2020 (*48*), apparently without testing for SARS-CoV-2 (*7*). Live animals sold at the market (Table 1) were apparently not sampled either. By contrast, during the SARS-CoV-1 outbreaks farms and markets remained open for over a year after the first human cases occurred, allowing sampling of viruses from infected animals (*20*).

The live animal trade and live animal markets are a common theme in virus spillover events (*21–23*, *50*), with markets such as the Huanan market selling live mammals being in the highest risk category (*51*). The events leading up to the

COVID-19 pandemic mirror the SARS-CoV-1 outbreaks from 2002-2004, which were traced to infected animals in Guangdong, Jiangxi, Henan, Hunan, and Hubei provinces in China (*20*). Maximum effort must now be applied to elucidate the upstream events that might have brought SARS-CoV-2 into the Huanan market, culminating in the COVID-19 pandemic. To reduce the risk of future pandemics we must understand, and then limit, the routes and opportunities for virus spillover.

Methods summary

Ethics statement

This research was reviewed by the Human Subject Protection Program at the University of Arizona and the Institutional Review Board at The Scripps Research Institute and determined to be exempt from IRB approval because it constitutes secondary research for which consent is not required.

Data sources

COVID-19 case data from December 2019 was obtained from the WHO mission report (*7*) and our previous analyses (*5*). Location information was extracted and sensitivity analyses performed to confirm accuracy and assess potential ascertainment bias. Geotagged January/February 2020 data from Weibo COVID-19 help seekers was obtained from the authors (*26*). Population density data was obtained from worldpop.org (*27*). Sequencing- or qPCR-based environmental sample SARS-CoV-2 positivity from the Huanan market was obtained from a January 2020 China CDC report (data S1) (*24*).

Wildlife trading at the Huanan market

Animal sales from Wuhan wet markets immediately prior to the COVID-19 pandemic was previously reported (*8*) and in this study we report details about animals for sale at the Huanan market up until November 2019.

Spatial analyses of COVID-19 cases

Haversine distances to the Huanan market were calculated for each of the geolocated December 2019 cases. Centerpoints and median distances from cases to the Huanan market were calculated separately for (1) all 155 cases, (2) the 35 cases epidemiologically linked to the Huanan market, (3) for the 120 cases not epidemiologically linked to the market, (4) the eleven lineage B cases, and (5) the earliest lineage A case. These distances were also calculated for the 737 Weibo help seekers from 8 January to 10 February 2020 (*26*). Empirical null distributions were generated from the population density data and the Weibo data. The population density null distributions were age-matched to the December 2019 cases.. Kernel density estimates were also generated for the market-linked cases, unlinked-cases and all cases, to infer a probability density function from which the cases could have been drawn. Highest-density contours representing specific probability masses (0.5, 0.25, 0.1, 0.05, and 0.01) were inferred and the location of the market compared to these.

Mobility analyses

To estimate the relative amount of intra-urban human traffic to the Huanan market compared to other locations within the city of Wuhan, we utilized a location-specific dataset of social media check-ins in the Sina Visitor System as shared by Li *et al.* 2015 (*33*). This dataset is based on 1,491,499 individual check-in events across the city of Wuhan from the years 2013-2014 (5-6 years before the start of the COVID-19 pandemic), and 770,521 visits are associated with 312,190 unique user identifiers. Location names and categories were translated using a Python API for Google Translate.

Spatial analyses of environmental samples at the Huanan market

We used the official maps from the China CDC (*12*) (data S1) and WHO map (*7*), as well as satellite photographs (Google Maps, Google Earth, Baidu Maps), aerial photographs, and images of the market in the public domain to reconstruct the floorplan of the market. Market stalls were assigned by categories of the types of goods sold using official reports and data from the TianYanCha.com business directory (table S8). Final maps of the Huanan market were converted into geojson format for spatial analyses. Significance testing of live animal vendors and/or human SARS-CoV-2 cases on the number of positive environmental samples was performed using a binomial GLM. Distances between businesses were defined as the distance between their respective centerpoints and spatial relative risk analysis was performed using the 'sparr' package in R, using linear boundary kernels for edge correction (*52*), with bandwidth selection performed using least squares cross-validation.

ACKNOWLEDGMENTS

We thank the researchers who generated the geospatial and environmental sample data and the members of the China team involved in producing the WHO mission report for the maps that made this work possible. We thank Michael Standaert, Bonnie LaFleur, @babarlelephant, Maciej Boni, Florence Débarre and Benjamin Pierce for comments and assistance. We thank worldpop.org for making population density and demographic data from Wuhan freely available. We thank both the patients and the clinicians and researchers whose data made this research possible. We thank five reviewers for insightful comments and feedback. **Funding:** This project has been funded in whole or in part with Federal funds from the National Institute of Allergy and Infectious Diseases, National Institutes of Health, Department of Health and Human Services, under Contract No. 75N93021C00015 (MW). JIL acknowledges support from the NIH (5T32AI007244-38). SAG acknowledges support from the NIH (F32AI152341). JEP acknowledges support from the NIH (T15LM011271). JOW acknowledges support from NIH (AI135992 and AI136056). DLR acknowledges support of the Medical Research Council (MC_UU_12014/12) and the Wellcome Trust (220977/Z/20/Z). MAS, PL and AR acknowledge the support of the Wellcome Trust (Collaborators Award 206298/Z/17/Z – ARTIC network), the European Research Council (grant agreement no. 725422 – ReservoirDOCS) and NIH grant R01AI153044. ALR is supported by the Canadian Institutes of Health Research as part of the Coronavirus Variants Rapid Response Network (CoVaRR-Net: CIHR FRN#175622) and acknowledges that VIDO receives operational funding from the Canada Foundation for Innovation – Major Science Initiatives Fund and from the Government of Saskatchewan through Innovation Saskatchewan and the Ministry of Agriculture. MK receives funding from the European Union's Horizon 2020 research and innovation program under grant agreement No. 874735 (VEO, Versatile Emerging infectious disease Observatory). RFG is supported by the NIH (R01AI132223, R01AI132244, U19AI142790, U54CA260581, U54HG007480, OT2HL158260), the Coalition for Epidemic Preparedness Innovation, the Wellcome Trust Foundation, Gilead Sciences, and the European and Developing Countries Clinical Trials Partnership Programme. ECH is supported by an Australian Research Council Laureate Fellowship (FL170100022). KGA is supported by the NIH (U19AI135995, U01AI151812, and UL1TR002550).

Contributions: Conceptualization: MW, KGA; Methodology: MW, JIL, AC-C, LM, JEP, MUGK, MAS, ALR, DLR, SAG, AR, JOW, RFG, PL, ECH, KGA; Software: LM, JIL, JEP, JOW, PL, AR; Validation: MW, LM, JIL, JEP, PL, JOW, KGA; Formal analysis: MW, JIL, AC-C, LM, JEP, MUGK, MAS, ALR, DLR, SAG, AR, JOW, RFG, PL, ECH, KGA; Investigation: MW, JIL, AC-C, LM, JEP, MUGK, MAS, MK, ALR, DLR, CN, SAG, AR, JOW, RFG, PL, ECH, KGA; Resources: MW, JOW, KGA; Data Curation: MW, AR, KGA; Writing - original draft preparation: MW, RFG; Writing - review and editing: MW, JIL, AC-C, LM, JEP, MUGK, MAS, MK, ALR, CN, DLR, SAG, AR, JOW, RFG, PL, ECH, KGA; Visualization: MW, JIL, LM, JEP, ALR, AR, JOW, RFG, PL, ECH, KGA; Supervision: MW, JOW, KGA; Project administration: MW, KGA. Funding acquisition: MW, JIL, AC-C, LM, JEP, MUGK, MAS, ALR, DLR, SAG, AR, JOW, RFG, PL, ECH, KGA. **Competing interests:** JOW receives funding from the CDC via contracts to his institution unrelated to this research. MAS receives funding from Janssen Research & Development, US Food & Drug Administration, and the US Department of Veterans Affairs via contracts and grants unrelated to this research. RFG is a co-founder of Zalgen Labs, a biotechnology company developing countermeasures for emerging viruses. MW, ALR, AR, MAS, ECH, SAG, JOW, and KGA have received consulting fees and/or provided compensated expert testimony on SARS-CoV-2 and the COVID-19 pandemic. MK has participated in the second WHO mission to China to study the origins of the pandemic and has served as scientific advisor on emerging disease preparedness to the Guangdong CDC prior to 2020. **Data and materials availability:** Data and code for this manuscript are available from (*53*). Fig. 1. Spatial patterns of COVID-19 cases in Wuhan in December 2019 and January-February 2020. (A) Locations of the 155 cases we extracted from the WHO mission report (7). Inset: map of Wuhan with December 2019 case indicated with gray dots. (No cases are obscured by the inset.) In both the inset and the main panel the location of the Huanan market is indicated with a red square. (B) Probability density contours reconstructed by a kernel density estimate (KDE) using all 155 COVID-19 cases locations from December 2019. The highest density 50% contour marked is the area for which cases drawn from the probability distribution are as likely to lie inside as outside. Also shown are the highest density 25%, 10%, 5%, and 1% contours. Inset showing an expanded view and the highest density 1% probability density contour. (C) Probability density contours reconstructed using the 120 COVID-19 cases locations from December 2019 that were unlinked to the Huanan market. (D) Locations of 737 COVID-19 cases from Weibo data dating to January and February of 2020. (E) The same highest probability density contours (50% through 1%) for 737 COVID-19 case locations from Weibo data.

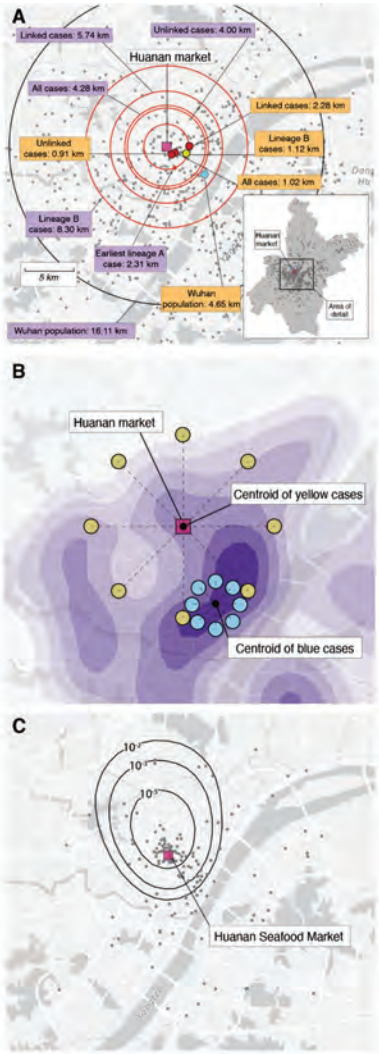

Fig. 2. **Spatial analyses.** (**A**) Inset: map of Wuhan, with gray dots indicating 1000 random samples from worldpop.com null distribution. Main panel: median distance between Huanan market and (1) worldpop.org null distribution shown with a black circle and (2) December cases shown by red circles (distance to Huanan market depicted in purple boxes). Center-point of Wuhan population density data shown by blue dot. Center-points of December case locations shown by red dots ('all', 'linked' and 'unlinked' cases); dark blue dot (lineage A cases); and yellow dot (lineage B cases). Distance from center-points to Huanan market depicted in orange boxes. (**B**) Schematic showing how cases can be near to, but not centered on, a specific location. We hypothesized that if the Huanan market epicenter of the pandemic then early cases should fall not just unexpectedly near to it but should also be unexpectedly centered on it (see Methods). The blue cases show how cases quite near the Huanan market could nevertheless not be centered on it. (**C**) Tolerance contours based on relative risk of COVID-19 cases in December, 2019 versus data from January-February 2020. The dots show the December case locations. The contours represent the probability of observing that density of December cases within the bounds of the given contour if the December cases had been drawn from the same spatial distribution as the January-February data.

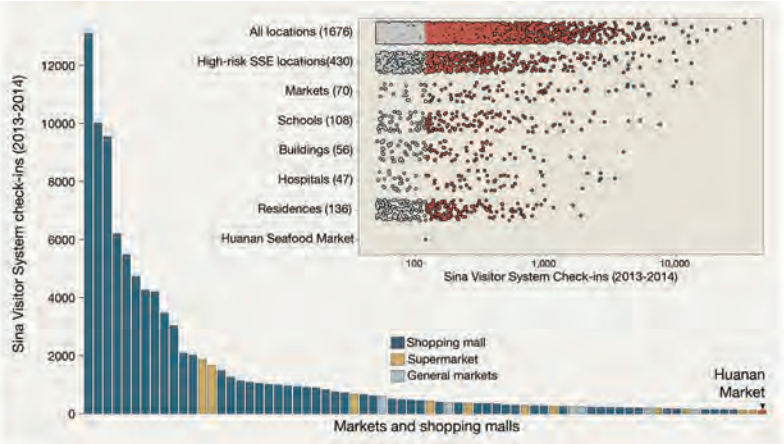

Fig. 3. Visitors to locations throughout Wuhan. Number of social media check-ins in the Sina Visitor System from 2013-2014 as shared by (*33*). Number of visitors to individual markets throughout the city are shown in comparison to the Huanan market. Inset: the total number of check-ins to all individual locations across the city of Wuhan, grouped by category. Locations with more than 50 visitor check-ins are shown, and the locations which received more check-ins than the Huanan market in the same period are shown in red.

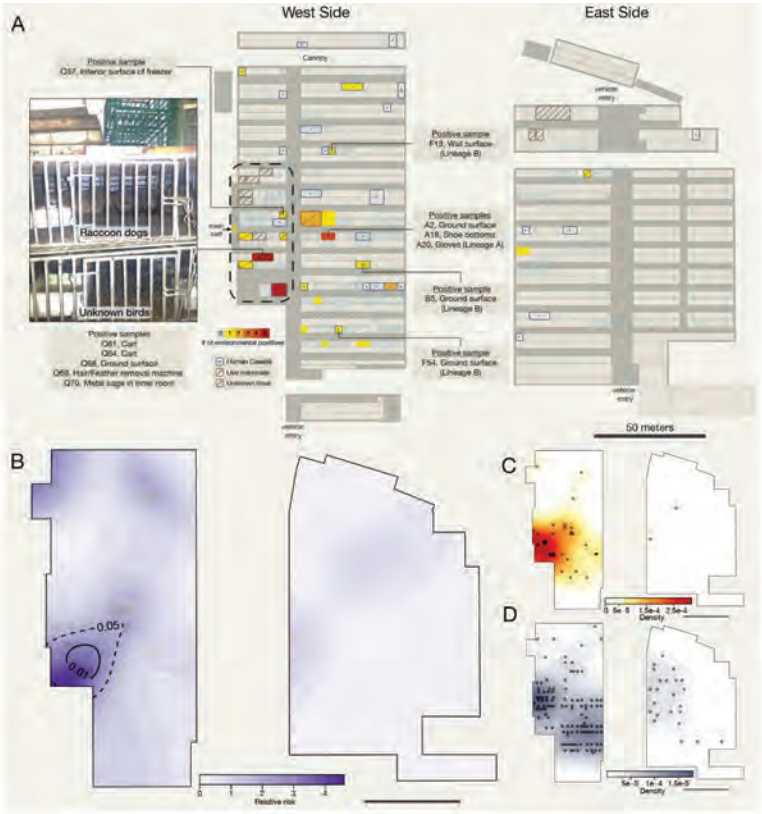

Fig. 4. Map of the Huanan Wholesale Seafood Market. (A) Aggregated environmental sampling and human case data from Huanan Market. Captions (left) describe the types of SARS-CoV-2 positive environmental samples obtained from known live animal vendors and (center) from stalls with samples with known virus lineage. Lineage is unknown unless noted; sequencing data has not been released for some samples and many samples were PCR-positive but not sequenced. Image (left) of raccoon dogs in a metal cage, on top of caged birds, taken in business with five positive environmental samples (photo credit: E.C.H.). Rectangle with dashed outline is used to denote the 'wildlife' section of the market. (B) Relative risk analysis of positive environmental samples. Tolerance contours enclose regions with statistically significant elevation in density of positive environmental samples relative to the distribution of sampled stalls. (C) Distribution of positive environmental samples. Sample locations (centroid of corresponding business) and quantity are shown as black circles. (D) Control distribution for relative risk analysis. All businesses investigated with environmental sampling are shown as black circles (one per business, whether or not a positive sample was found). See table S12 for details on stalls that were SARS-CoV-2-negative.

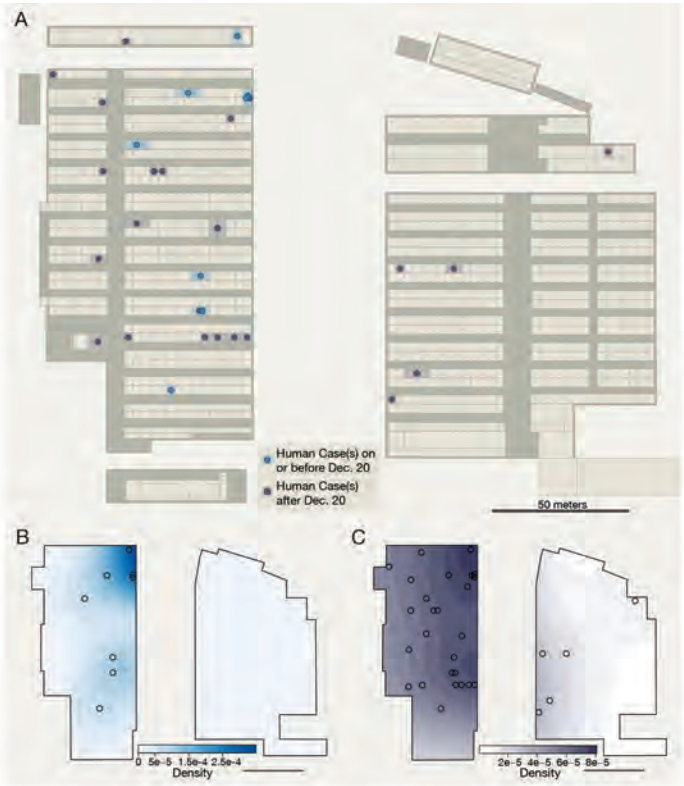

Fig. 5. Location and timing of human cases in Huanan market. (**A**) Outline colors correspond to the timing of the first known case in each business. Individual case timing is denoted by marker color and shown within the outlined business. (**B**) Distribution of known cases on or before December 20th, 2019. Locations of each case are shown as a black circle. (**C**) Distribution of all known human cases in Huanan Market. See table S11 for details on SARS-CoV-2 positive human cases with the Huanan market.

Table 1. Live mammals traded at the Huanan market in November and December 2019

Species (susceptibility*)	Family (susceptibility*)	Order (susceptibility*)	Observed at Huanan market, November 2019
Raccoon dog (*Nyctereutes procyonoides*) (Y)	Canidae (Y)	Carnivora (Y)	Y
Amur hedgehog (*Erinaceus amurensis*)	Erinaceidae	Eulipotyphla	Y
Hog badger (*Arctonyx albogularis*) (Y)	Mustelidae (Y)	Carnivora (Y)	Y
Asian badger (*Meles leucurus*)	Mustelidae (Y)	Carnivora (Y)	Y
Chinese hare (*Lepus sinensis*)	Leporidae (Y)	Lagomorpha (Y)	Y
Chinese bamboo rat (*Rhizomys sinensis*) (Y)	Spalacidae (Y)	Rodentia (Y)	Y
Malayan porcupine (*Hystrix brachyura*)	Hystricidae	Rodentia (Y)	Y
Chinese muntjac (*Muntiacus reevesi*)	Cervidae (Y)	Artiodactyla (Y)	Y
Marmot (*Marmota himalayana*)	Sciuridae	Rodentia (Y)	Y
Red fox (*Vulpes vulpes*) (Y)	Canidae (Y)	Carnivora (Y)	Y
Siberian weasel (*Mustela sibirica*)	Mustelidae (Y)	Carnivora (Y)	N†
Pallas's squirrel (*Callosciurus erythraeus*)	Sciuridae	Rodentia (Y)	N
Masked palm civet (*Paguma larvata*) (Y)	Viverridae (Y)	Carnivora (Y)	N
Coypu (*Myocastor coypus*)	Echimyidae	Rodentia (Y)	N
Mink (*Neovison vison*) (Y)	Mustelidae (Y)	Carnivora (Y)	N
Red squirrel (*Sciurus vulgaris*)	Sciuridae	Rodentia (Y)	N
Wild boar (*Sus scrofa*) (Y)	Suidae (Y)	Artiodactyla (Y)	N
Complex-toothed flying squirrel (*Trogopterus xanthipes*)	Sciuridae	Rodentia (Y)	N

*Based on live susceptibility findings, serological findings, or ACE2-binding assays. See table S5 for details and associated references.
†Animals listed as "No" were, however, present at Wuhan markets during the 2017–2019 study period (*8*).

Statement on Misinformation about SARS-CoV-2 Origins

To date, the origin of the SARS-CoV-2 virus that caused the COVID-19 pandemic has not been identified, despite intensive efforts to do so. This is not unusual — confirming with 100% certainty the origin of a virus is a long and complicated process. It took 14 years for scientists to find a single bat population that contained all the necessary genetic components of SARS-CoV, the virus that caused the 2003 SARS epidemic. We still do not know the origins of the 2014 Ebola outbreak.

Unfortunately, in the absence of a definitive answer, misinformation and disinformation are filling the void, which does more harm than good. NIH wants to set the record straight on NIH-supported research to understand naturally occurring bat coronaviruses at the Wuhan Institute of Virology, funded through a subaward from NIH grantee EcoHealth Alliance. Analysis of published genomic data and other documents from the grantee demonstrate that the naturally occurring bat coronaviruses studied under the NIH grant are genetically far distant from SARS-CoV-2 and could not possibly have caused the COVID-19 pandemic. Any claims to the contrary are demonstrably false.

The scientific evidence to date indicates that the virus is likely the result of viral evolution in nature, potentially jumping directly to humans or through an unidentified intermediary animal host. Historically, many viruses have emerged from animals to cause epidemics and pandemics, including influenza, Ebola, Zika, West Nile fever, SARS, and more. Importantly, after an intensive investigation, agencies in the U.S Intelligence Community agreed that the virus was not developed as a biological weapon and most agencies assessed that SARS-CoV-2 most likely was not genetically engineered.

Public health and scientific organizations, including NIH, are intensely interested in getting a definitive answer to inform efforts to prevent future events. This effort would benefit from less speculation and more scientific cooperation, especially from China, without which the SARS-CoV-2 origins will be impossible to identify.

Executive Summary

Research involving pathogens is essential to global health and security. Such research provides insight into the fundamental nature of human-pathogen interactions, enables the assessment of the pandemic potential of emerging infectious agents, and informs public health and preparedness efforts, including the development of medical countermeasures. Several federal policies are in place to help ensure that pathogen research is conducted safely and in ways that minimize the risks of laboratory accidents and security risks. A number of biosafety incidents at Federal facilities in 2014 prompted renewed efforts to promote and enhance biosafety and biosecurity. Concerns were also raised about certain "gain-of-function" (GOF) studies with the potential to generate pathogens with pandemic potential. The concerns centered on whether a pathogen with enhanced transmissibility and/or virulence could be accidentally or intentionally released from a laboratory, potentially exposing surrounding populations and possibly causing a wider pandemic.

The U.S. government (USG), as part of its continued focus on biosafety and biosecurity, undertook a deliberative process to carefully examine the risks and benefits associated with certain GOF studies. The deliberative process involved the National Science Advisory Board for Biosecurity (NSABB), which was tasked with making recommendations to the USG on this topic, and the National Academies of Sciences, Engineering, and Medicine (National Academies), which was tasked to convene two public symposia to generate broad discussion on relevant issues. To further inform NSABB deliberations, the National Institutes of Health (NIH) commissioned two studies – an independent assessment of the risks and benefits associated with GOF studies, conducted by Gryphon Scientific, and an ethical analysis of the issues related to funding and conducting such studies, performed by Professor Michael Selgelid.

The NSABB was charged with advising on the design of the risk and benefit assessments (RBA) for GOF studies and with providing recommendations to the USG on a conceptual approach for evaluating proposed GOF studies. In May 2015 the NSABB issued its *Framework for Guiding the Conduct of Risk and Benefit Assessments of Gain-of-Function Research*, which guided NIH in overseeing the contractor conducting the RBA. In May 2016, informed by the results of the RBA as well as its analysis of the current policy landscape, consideration of relevant ethical issues, and consultations with domestic and international stakeholders, the NSABB finalized the report that follows – *Recommendations for the Evaluation and Oversight of Proposed Gain-of-Function Research* – which describes the Board's analyses and findings, and articulates its recommendations to the USG for the evaluation and oversight of proposed GOF studies.

NSABB Findings:

Finding 1. There are many types of GOF studies and not all of them have the same level of risks. Only a small subset of GOF research—GOF research of concern (GOFROC)—entail risks that are potentially significant enough to warrant additional oversight.

Finding 2. The U.S. government has several policies in place for identifying and managing risks associated with life sciences research. There are several points throughout the research life cycle where, if the policies are implemented effectively, risks can be managed and oversight of GOF research of concern could be implemented.

Finding 3. Oversight policies vary in scope and applicability, and do not cover all potential GOFROC, therefore, current oversight is not sufficient for all GOF research of concern.

Finding 4. An adaptive policy approach is a desirable way to ensure that oversight and risk mitigation measures remain commensurate with the risks associated with the research and that the benefits of the research are being fully realized.

Finding 5. There are life sciences research studies, including possibly some GOF research of concern, that should not be conducted because the potential risks associated with the study are not justified by the potential benefits. Decisions about whether specific GOFROC should be permitted will entail an assessment of the potential risks and anticipated benefits associated with the individual experiment in question. The scientific merit of a study is a central consideration during the review of proposed studies but other considerations, including legal, ethical, public health, and societal values are also important and need to be taken into account.

Finding 6. Managing risks associated with GOF research of concern, like all life sciences research, requires both federal and institutional oversight, awareness and compliance, and a commitment by all stakeholders to safety and security.

Finding 7. Funding and conducting GOF research of concern encompasses many issues that are international in nature.

NSABB Recommendations to the U.S. government:

Recommendation 1. Research proposals involving GOF research of concern entail significant potential risks and should receive an additional, multidisciplinary review, prior to determining whether they are acceptable for funding. If funded, such projects should be subject to ongoing oversight at the federal and institutional levels.

As part of this recommendation, the NSABB has proposed a conceptual approach for guiding funding decisions about GOFROC. First, the NSABB identified the attributes of GOFROC, which is research that could generate a pathogen that is: 1) highly transmissible and likely capable of wide and uncontrollable spread in human populations; and 2) highly virulent and likely to cause significant morbidity and/or mortality in humans. Next, the NSABB identified a set of principles that should guide funding decisions for GOFROC. Only research that is determined to be in line with these principles should be funded. Additional risk mitigation measures may be required for certain research studies to be deemed acceptable for funding.

Recommendation 2. An advisory body that is designed for transparency and public engagement should be utilized as part of the U.S. government's ongoing evaluation of oversight policies for GOF research of concern.

Recommendation 3. The U.S. government should pursue an adaptive policy approach to help ensure that oversight remains commensurate with the risks associated with the GOF research of concern.

> **Recommendation 3.1.** The U.S. government should develop a system to collect and analyze data about laboratory safety incidents, near-misses, and security breaches as well as the effectiveness of mitigation measures to inform GOF research of concern policy development over time.
>
> **Recommendation 3.2.** The U.S. government should develop or facilitate the development of a system to collect and analyze data about Institutional Review Entity (IRE) challenges, decisions, and lessons learned to provide feedback to the IRE community and to inform policy development for GOF research of concern over time.

Recommendation 4. In general, oversight mechanisms for GOF research of concern should be incorporated into existing policy frameworks when possible.

Recommendation 5. The U.S. government should consider ways to ensure that all GOF research of concern conducted within the U.S. or by U.S. companies be subject to oversight, regardless of funding source.

Recommendation 6. The U.S. government should undertake broad efforts to strengthen laboratory biosafety and biosecurity and, as part of these efforts, seek to raise awareness about the specific issues associated with GOF research of concern.

Recommendation 7. The U.S. government should engage the international community in a dialogue about the oversight and responsible conduct of GOF research of concern.

1. Introduction

A robust life sciences research enterprise is necessary to counter the continually evolving threats to public health and national security posed by endemic and emerging pathogens, as well as malicious biological threats. By helping to define the nature of human-pathogen interactions, life sciences research promotes public health and national security not only by enhancing our understanding of pathogen biology and disease pathogenesis, but also by informing biosurveillance and medical countermeasure development. Such research can also aid in the assessment of the pandemic potential of emerging infectious agents, thereby underpinning health policy decisions and preparedness and response efforts.

While the ultimate goal of life sciences research involving pathogens is the protection and promotion of public health, there are inherent associated biosafety and biosecurity risks. Potential risks might arise from laboratory accidents or security breaches that result in laboratory acquired infections or the accidental or deliberate release of a pathogen from containment. Life sciences research also has "dual use" potential. That is, legitimate research may generate information, products, or technologies that could be misused to threaten public health or national security. To mitigate such dual use concerns, as well as potential biosafety and biosecurity risks, research involving pathogens is subject to multiple layers of federal and institutional oversight.

The Gain-of-Function Debate and the U.S. Government Response

Experimental techniques and approaches that modify microorganisms are routinely employed in pathogen research to ascertain the roles of genes and their functional products. Such studies are fundamental to the field of microbiology and facilitate correlation of genetic and phenotypic characteristics – a critical step in deciphering the complex nature of host-pathogen interactions that underlie transmission, infection, and pathogenesis. Such manipulations can result in either diminished (loss-of-function) or enhanced (gain-of-function) biological phenotypes (see Box 1).

Studies that result in the generation of pathogens with enhanced, or gain-of-function (GOF), phenotypes are conducted for a number of valid scientific purposes. Such studies provide information that adds to the scientific knowledge base and can inform biosurveillance, medical countermeasure development, and public policy decision-making related to public health and preparedness. The vast majority of such GOF studies do not raise significant safety or security concerns. However, certain GOF studies involving pathogens have raised concerns about whether a laboratory-generated pathogen with pandemic potential could be accidentally or intentionally released, resulting in significant consequences to public, or perhaps, global health. Concerns have also been raised about whether certain GOF studies could generate information that could enable individuals with malevolent intent to generate a pathogen with pandemic potential.

The controversy over certain GOF studies arose after two groups demonstrated that highly pathogenic avian influenza H5N1 viruses with a small number of experimentally-induced mutations became transmissible between mammals by respiratory droplets.[1,2] In 2012, in response to the controversy associated with publication of the manuscripts describing these findings, the influenza community initiated a voluntary suspension of certain GOF studies involving highly pathogenic avian influenza H5N1 viruses. During that time, policymakers considered whether certain GOF studies should be conducted using federal funds, and if so, how those studies could be safely conducted. The Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) issued new biosafety guidelines for working with highly pathogenic avian influenza strains.[3,4] The U.S. Department of Health and Human Services (HHS) developed a framework for guiding its funding decisions about GOF projects that may generate H5N1 or H7N9 avian influenza viruses that are transmissible between mammals by respiratory droplets.[5,6]

Concerns regarding laboratory safety and biosecurity were renewed following a number of biosafety incidents at U.S. Federal laboratories reported during the summer of 2014. The incidents did not involve GOF studies *per se* but raised broader concerns about laboratory safety and security as it applies to pathogen research.

Box 1. Gain-of-Function Research

Recently, the phrase "gain-of-function research" has become synonymous with certain studies that enhance the ability of pathogens to cause disease. However, gain-of-function studies, as well as loss-of-function studies, are common in molecular microbiology and are essential to understanding molecular pathogenesis of infectious diseases. Changes to the genome of an organism, whether naturally occurring or directed through experimental manipulations in the laboratory, can result in altered phenotypes, as biological functions are lost or gained. Investigators routinely conduct loss- and gain-of-function experiments to understand the complex nature of host-pathogen interactions that underlie transmission, infection, and pathogenesis.

The term "gain-of-function" is generally used to refer to changes resulting in the acquisition of new, or an enhancement of existing, biological phenotypes. This report further defines "gain-of-function research of concern" to describe the subset of studies that have been the subject of recent debate and have raised potential biosafety and biosecurity implications. These are gain-of-function studies with the potential to generate pathogens with pandemic potential in humans by exhibiting high transmissibility and high virulence. See Section 6 for a more rigorous description of GOF research of concern (GOFROC).

As one component of comprehensive efforts to review and enhance laboratory biosafety and biosecurity, the U.S. government (USG) embarked on a deliberative process to re-evaluate the risks and benefits of certain GOF research with a goal of developing policy governing the funding and conduct of such research.[7] The deliberative process involved the National Science Advisory Board for Biosecurity (NSABB), which served as the official federal advisory body for providing advice in this area, and the National Academies of Sciences, Engineering, and Medicine (National Academies), which fostered broader scientific and public discussions on the topics. To inform NSABB deliberations, NIH commissioned formal risk and benefit assessments (RBA) of GOF research involving pathogens with pandemic potential and a separate analysis of ethical issues surrounding the conduct of such studies. Stakeholder input was also essential to the process.

The deliberative process was accompanied by a pause in the provision of new federal funds for certain GOF research involving influenza, Middle East Respiratory Syndrome (MERS) or Severe Acute Respiratory Syndrome (SARS) viruses—pathogens determined to have pandemic potential. Specifically:

> *New USG funding will not be released for gain-of-function research projects that may be reasonably anticipated to confer attributes to influenza, MERS, or SARS viruses such that the virus would have enhanced pathogenicity and/or transmissibility in mammals via the respiratory route. This restriction would not apply to characterization or testing of naturally occurring influenza, MERS, and SARS viruses, unless the tests are reasonably anticipated to increase transmissibility and/or pathogenicity.*[8]

In parallel, the USG encouraged the research community (both those who receive USG funding and those who do not) to join in adopting a voluntary pause on any ongoing research that involves the types of studies that are subject to the funding restriction above.

NSABB recommendations conveyed in this report will inform the USG as it develops policy about whether certain types of GOF studies on pathogens with pandemic potential should be supported and, if so, how such research proposals should be evaluated to inform funding and oversight decisions. It is expected that the temporary funding pause will be lifted and/or replaced by a decision or policy that addresses GOF research involving the generation of pathogens with pandemic potential.

[8] Ibid.

2. NSABB Charge

On October 22, 2014, as part of the USG's deliberative process for GOF studies, the NSABB was issued its charge to:

1. Advise on the design, development, and conduct of risk and benefit assessments for GOF studies, and
2. Provide recommendations to the U.S. government on a conceptual approach to the evaluation of proposed GOF studies

In developing its recommendations the NSABB was asked to consider: the results of the risk and benefit assessments; the discussions hosted by the National Academies; the spectrum of potential risks and benefits associated with GOF studies; and any alternative methods that may be employed to yield similar scientific insights or benefits, while reducing potential risks.

Since gain-of-function studies encompass a broad spectrum of pathogens and experimental manipulations, the NSABB discussed its charge and sought to identify the appropriate scope for its deliberations. Since the experiments that initiated the controversy involved the generation of pathogens that were concerning from a human health perspective, NSABB deliberations and recommendations focus on pathogens that pose risks to human populations. NSABB recommendations also focus on guiding USG funding decisions but the Board also considered issues associated with non-federally funded research and international research.

3. NSABB Deliberative Approach

The deliberative process (Figure 1) initiated by the USG to evaluate the risks and benefits of GOF studies involved the NSABB and the National Academies. To address its charge, NSABB formed two working groups to develop draft recommendations, which were then discussed by the full Board[9]. The National Academies convened public forums to stimulate broad discussions and receive additional stakeholder input. The first forum was held early in the deliberative process and a second was held in March 2016; both were designed to inform NSABB deliberations.

To inform the deliberative process further, NIH commissioned two additional analyses: 1) qualitative and quantitative risk and benefit assessments of GOF research, conducted by Gryphon Scientific, and 2) a review of the ethical considerations associated with the GOF issue and an analysis of relevant ethical decision-making frameworks, conducted by Dr. Michael Selgelid.

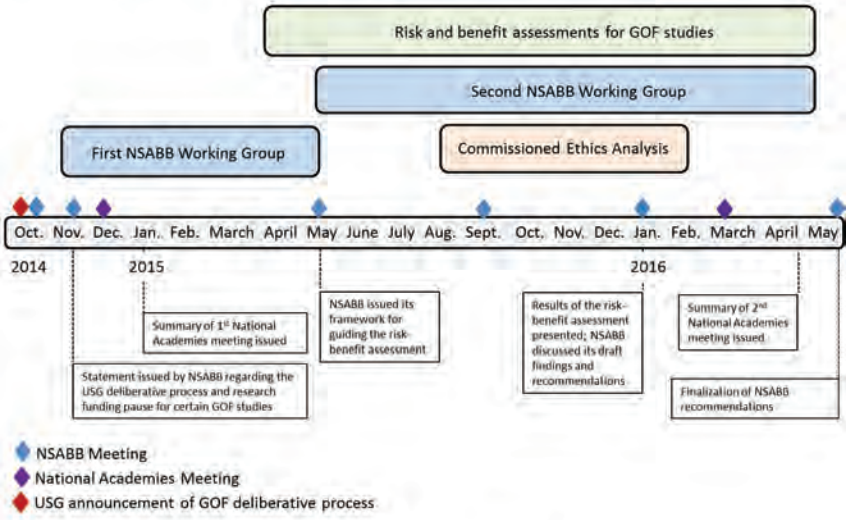

Figure 1. Timeline and major events of the GOF deliberative process.

[9] Information about these meetings and activities, including agendas, summaries, and archived videocasts, can be found on the NSABB website at: http://osp.od.nih.gov/office-biotechnology-activities/biosecurity/nsabb/nsabb-meetings-and-conferences/past-meetings

The NIH Office of Science Policy, which administers the NSABB, managed the overall deliberative process. NIH oversaw the work of its contractors, Gryphon Scientific and Dr. Michael Selgelid, and interfaced between the NSABB and contracted entities.

More information regarding the process and NSABB deliberations may be found in Appendices. Appendix A provides a detailed description of the NSABB's deliberative approach. Appendix B summarizes the current U.S. policy landscape for the oversight of pathogen research. Appendix C describes examples of studies that would or would not be considered GOF research of concern. Appendix D provides an overview of stakeholder views that were presented and considered by NSABB. Appendix E lists the experts and sources consulted by NSABB, including those who submitted public comments. Appendix F and G list the NSABB roster and charter. NSABB's *Framework for Guiding the Conduct of Risk and Benefit Assessments of Gain-of-Function Research*, which was approved by the Board in May 2015, is provided in Appendix H.

Guiding Principles for NSABB Deliberations

Early in the overall process the NSABB developed the principles below to guide its deliberations and underpin its analysis of the risk and benefit assessments.

1. The NSABB deliberations should focus on defining the GOF problem then include broad consideration of possible solutions. A range of approaches and decision-making frameworks will be considered, and the NSABB will take into account these various approaches when developing its recommendations.

2. NSABB will consider the potential risks and benefits of a broad range of GOF studies involving influenza, SARS, and MERS viruses in order to identify those that may raise significant concerns that should be addressed. However, the NSABB will aim to develop recommendations that are grounded in broadly-applicable concepts and principles that could, if necessary, apply to GOF studies involving other pathogens that may require evaluation in the future.

3. Similarly, NSABB will consider the risks and benefits associated with alternative research approaches to GOF research to understand whether or not these may substitute for or complement GOF studies.

4. NSABB recommendations will be informed by data and information about potential risks and benefits as well as values that will guide the evaluation and comparison of these risks and benefits. Ethical, societal, and legal considerations will also contribute to the development of recommendations and these inputs should be explicitly identified, discussed, and prioritized.

5. NSABB recognizes that not all analyses relevant to its task are quantitative and that uncertainties inherent in any quantitative analysis may remain. NSABB will seek to document important areas of uncertainty in any data or analysis when necessary.

6. NSABB should publicly debate its draft recommendations and describe in its report any dissenting views that may vary substantially from the Board's recommendations.

7. NSABB should consider current USG policies and guidelines, determine whether they adequately address risks associated with GOF research (in light of potential benefits), and make recommendations that are consistent with that determination. Current policies may be adequate or require only minor changes; alternatively, significant enhancements may be needed. The adequacy of current policy to cover GOF studies may vary by pathogen. Recognizing the paramount importance of ensuring safety, security, and public health, policies should also minimize the burdens placed upon the conduct of science.

8. NSABB recommendations will inform the development of U.S. government policy, which will apply to research funded, conducted, or overseen by the U.S. government either domestically or internationally. NSABB will be mindful in its deliberations of the likelihood that the Board's recommendations and U.S. policy decisions will also influence other governments and non-USG funders of life sciences research.

9. The NSABB will also consider whether there are certain studies that should not be conducted under any circumstances, and if so, articulate the critical characteristics of such studies.

10. Maintaining public trust and confidence in life sciences research is critical and must be taken into account as recommendations are formulated.

4. Analysis

In developing recommendations on a conceptual approach for evaluating GOF proposals, NSABB examined three major areas: the current policy landscape for overseeing research involving pathogens, the ethical issues associated with funding and conducting GOF studies, and the results of the risk and benefit assessments of GOF research. In addition, the NSABB considered broad stakeholder perspectives through presentations from domestic and international experts at working group and full NSABB meetings, analysis of published articles, and comments from attendees at NSABB meetings or public comments submitted to the Board.

4.1. Analysis and Interpretation of the Risk and Benefit Assessment

The NSABB reviewed the risk and benefit assessments conducted by Gryphon Scientific, which were designed to evaluate the risks and benefits of GOF research in a manner that encompassed both benign and worrisome aspects of a broader range of GOF studies than those that have raised concerns. The RBA analyzed biosafety and biosecurity risks as well as possible benefits. Overall, the RBA includes a commendable amount of sophisticated work and analysis, is generally well-done, and largely achieves the goals it was intended to address. Gryphon's draft RBA report was made publically available in December 2015 and key results were presented and discussed at NSABB and National Academies meetings. The final report was issued in April 2016 and is available on Gryphon's website.[10]

Strengths of the Risk and Benefit Assessments

The RBA has significant strengths. It is a thorough and extensive analysis of the risks and benefits of GOF work in the context of the guidance provided in the NSABB *Framework for Conducting Risk and Benefits Assessments of Gain-of-Function Research*.[11] It takes into account the principles articulated in the framework and includes the agents, categories of possible risks, types of possible benefits, and possibly concerning scenarios and phenotypes that were laid out in the *Framework*. It was agreed that a few items from the *Framework* not be analyzed or focused on in the RBA so that the most probable issues of concern could be thoroughly addressed within the available time and resources.[12]

The biosafety risk assessment does a credible job of defining the relative risks associated with potential laboratory accidents involving GOF manipulations of pathogens with enhanced characteristics as compared to wild-type pathogens. This analysis is performed in a semi-quantitative way; it uses

[10] *Risk and Benefit Analysis of Gain-of-Function Research, Final Report*. Gryphon Scientific, April 2016. http://www.gryphonscientific.com/wp-content/uploads/2016/04/Risk-and-Benefit-Analysis-of-Gain-of-Function-Research-Final-Report.pdf

[12] National Science Advisory Board for Biosecurity Meeting, May 5, 2015. http://osp.od.nih.gov/office-biotechnology-activities/event/2015-05-05-120000-2015-05-05-200000/national-science-advisory-board-biosecurity-nsabb-meeting

appropriate, established, peer-reviewed methods to the extent available. The parametric approach employed is powerful and allows consideration of many situations of interest.

The report effectively illustrates that the harmful events being modeled are low probability (see Figures 6.2 and 6.4 in Gryphon's report). Only a small fraction of laboratory accidents would result in a loss of containment. Of those, only a small fraction would result in a laboratory acquired infection, and of those, only a fraction would spread throughout the surrounding community (or to the global population). The NSABB recognizes the challenge of analyzing low-probability, high-consequence events for which little data exists and appreciated attempts to make this point clear in the RBA.

The biosecurity risk assessment is primarily qualitative, and highlights analysis of previous malevolent events and evasions of security systems, likely capabilities and motivations of various possible actors, and an evaluation of the systems in place to prevent biosecurity breaches. Information was obtained from a survey of literature and discussions with biosecurity, intelligence, and law enforcement professionals. It is an extensive gathering of a wide range of information that has not been presented before in one place.

The information risk assessment (an element of the biosecurity risk assessment) is a qualitative analysis of risks that may result from the misuse of information derived from certain GOF studies that might be published in the future. It identifies information that might be attractive to malicious actors and compares it to other sources of information they might find attractive.

The benefits assessment uses a novel approach to assess potential benefits of GOF studies, a difficult task with little prior methodology to draw upon. The results are not quantitative, and attempts at quantification would have been appreciated. However, as is, the assessment may be the best that can be done with the available information and analytic tools. The benefits assessment thoroughly analyzes the possible benefits of alternatives to GOF studies and identifies areas where GOF research appears to provide unique benefits (i.e., benefits that are not attainable without the use of GOF), either currently or in the near future.

The RBA contains a number of other useful analyses as well, including background and contextual information on the biology of influenza and coronavirus, historical analysis of naturally-occurring seasonal and pandemic influenza and coronavirus outbreaks, an examination of the potential proliferation of GOF research, and analysis of the potential loss of public trust in science that could result if a laboratory incident involving GOF research were to occur. Significantly, the historical analysis notes that each year, influenza infects 5 – 10% of the world's population, resulting in significant morbidity and mortality (up to 500,000 deaths per year). This description of naturally-occurring influenza (and coronavirus) infections helps to establish the extant risks associated with these infectious diseases to which the risks associated with GOF studies might be compared.

Overall, the RBA is comprehensive, objective, reasonable, and generally extensively documented.

Limitations of the Risk and Benefit Assessments

The RBA also has some weaknesses and limitations that should be noted. First, the RBA was limited to the types of labs traditionally funded by the Federal government, which may not be representative of other settings where GOF research may be conducted. Every attempt was made to base the analyses in the RBA on scientific information and data. Nevertheless, data on the properties of the various pathogens being examined, events such as laboratory accidents or security breaches, or possible future acts of terrorism, are limited in some cases and unavailable in principle in others. Therefore, assumptions and estimations were necessary. For this reason, the biosafety risk assessment is not fully quantitative, primarily because absolute, quantitative baselines for the risk of work with wild-type pathogens could not be estimated with any certainty. Thus, the data presented are primarily comparative, and provide relative, rather than absolute, values for the risks associated with laboratory accidents involving GOF studies.

Gryphon compared the risks associated with potential lab accidents involving a GOF strain with the risks associated with the same accident involving a wild-type strain. This comparative approach is adequate for some scenarios but inadequate for others. For example, an increased risk associated with a GOF study that is relatively large (5-10-fold or greater) may appear significant, but if this increase is in comparison to a very small risk baseline, the overall risk associated with the GOF study may not be significant or concerning. Similarly, small increases in risk over a higher risk baseline, in fact, may be concerning. Additionally, differences in risk that are relatively small (about 2-fold) are difficult to interpret because such changes may fall within the limits of uncertainty for the analysis. Attempts to include some absolute baseline estimates of risk (an admittedly difficult task) were included in Section 6.8 of Gryphon's report. However, the lack of comprehensive estimates of baseline risk make interpreting the biosafety risks a challenge.

Given the comparative approach undertaken for the biosafety risk assessment, the implications of the results of this analysis depend a great deal on the wild-type comparator strains that were selected for the analysis. For instance, for pandemic influenza Gryphon initially selected the 1918 influenza strain as the comparator. Gryphon regarded this strain as embodying the maximum risk for influenza, yet a level of risk that is also deemed as acceptable given that research with this strain is permitted. However, using 1918 influenza as the comparator for the analysis compares GOF risks to a relatively high level of baseline risk, making the changes in risk associated with GOF manipulations comparatively small. Utilizing different comparator strains alters the relative risks associated with GOF manipulations. Using a high-risk baseline strain may obscure significant risks associated with GOF studies whereas using a strain with a low risk baseline may inflate the potential risks associated with GOF studies.

Little data exists about the probabilities of the accidents that initiate the chain of events that may lead to a pandemic and therefore, the quantitative probability of these accidents could not be incorporated into the biosafety risk assessment. The modeling of secondary spread of a pathogen through populations once it is released from a laboratory allows for some estimation of the consequences of an event, but without a better understanding of the likelihood that an accident would result in loss of containment or a laboratory acquired infection it is difficult to make judgments about the overall risk.

Gryphon's analysis accounts for this by presenting relative, actuarial risk. However, this approach results in the challenges associated with comparing relative risks described above. There are large uncertainties in most of the input parameters that are the basis for the biosafety risk calculations. Uncertainties about inferring absolute risk from these relative risks exist and were kept in mind as the Board developed its findings and recommendations.

The biosecurity risk assessment attempts to examine how GOF studies add to the risk of malevolent acts. Portions of the biosecurity risk assessment focus on GOF studies but others describe the type of threats that could occur against any high-containment laboratory. The semi-quantitative portion of the biosecurity risk assessment estimates probabilities for escape and secondary spread and escape from local control for various pathogens and event types. However, this analysis (see section 7.4 and Table 7.7 in Gryphon's report) assumes that 1, 5, or 10 individuals are initially infected as a result of a malicious act with no indication of how likely such an event would be, since there is no way to make such an estimate.

While exhaustively documented, the RBA is not always transparent about data reliability. In particular, interviews were used to gather much critical information, and this was not always well documented in a way that reflects how robust the resulting information may be. For peer-reviewed publications, this is less of a concern.

While evaluation of the benefits of alternatives to GOF studies is extensive, evaluation of risks of alternative approaches is not as thorough. In addition, risks and benefits are not presented in comparable terms, making it a challenge to determine whether certain risks are justified by potential benefits. Significantly, the benefit assessment is not quantitative and there is no probability analysis or attempt to estimate the likelihood that a certain benefit would be realized or what its impact might be.

Key Results of the Risk and Benefit Assessments

While NSABB considered all of the analyses in the RBA, some results are important to highlight. In general, the RBA examined risks and benefits associated with the major GOF phenotypes with the intention of identifying types of studies that would be most and least concerning, based particularly on their risk profile.

With regard to biosafety risks, only some potential GOF phenotypes represent substantially increased (5- to 10-fold or more) risks over the starting strain. Two-fold changes most likely fall within the uncertainty of the data, and while small differences might be important if it could be shown that they are significant, this demonstration is probably difficult. For coronaviruses, GOF studies that would create strains with increased transmissibility among mammals may entail significant risks if they also increase human transmission. The risks, were this combination to occur, would include increased probability of an outbreak escaping local control and increased likelihood of global consequences. In addition, experiments that enhance coronavirus growth in culture would likely increase the possibility of laboratory acquired infections.

For seasonal influenza, the GOF phenotypes entailing the greatest risks include enhanced transmission in mammals (assuming this increases transmission in humans), enhanced virulence, and evasion of immunity. Enhanced pathogenicity might significantly increase the global consequences of an outbreak.

For pandemic influenza, the issue of what GOF phenotypes could increase risk is highly dependent on the comparator strain used. If 1918 influenza is modified so that it is able to evade residual immunity, it could become more of a threat than 1957 H2N2, the comparator Gryphon used. For 1957 H2N2, enhancement of pathogenicity to that of 1918 also significantly increases risk. Other phenotype changes had little effect. However, if less transmissible and/or less virulent pandemic strains were used as the basis for comparison, the risks of some other GOF studies would appear to increase risk more significantly.

For avian influenza, the GOF experiments that lead to enhanced transmissibility in mammals (and presumably humans) would likely lead to an increased probability of local and widespread outbreaks, as well as increased global consequences. More subtle aspects of these very general conclusions may be found in the biosafety risk section and the Executive Summary of Gryphon's RBA report.

In general, GOF studies that were not considered by the NSABB to entail significant risks were those that would: adapt human pathogens to mammals to generate animal models; enhance the growth of attenuated vaccine strains; and antigenic drift studies that are commonly used to guide vaccine selection.

The biosecurity risk assessment shows that the most probable threats involve insiders who have direct access to dangerous pathogens or outsiders who collaborate with or subvert insiders. If currently mandated biosecurity systems are effective, outsiders have little chance of causing harm on their own. The RBA report also concludes that the risks associated with information from future GOF studies with influenza, SARS or MERS appear small; this is because most of the information of interest is already published, or non-GOF information relating to pathogens that are more attractive to individuals with malevolent intent is readily available. However, future scientific advancements could alter this assessment.

Most GOF studies provide benefits in the form of new scientific knowledge, and some of these benefits are unique (i.e., unable to be achieved by alternative, non-GOF approaches). While some GOF studies are likely to provide unique near-term benefits, these are associated with specific agents and phenotypes. With regard to more applied benefits, such as countermeasure development and biosurveillance, the most clear-cut example is experiments that increase growth of seasonal influenza vaccine candidates in culture. These studies provide unique benefits to current production of seasonal influenza vaccines, and likely will in the future. Another reasonably clear unique benefit is derived from experiments that enhance mammalian pathogenicity of coronaviruses as a means of developing animal models for studying disease and developing countermeasures. GOF studies that yield phenotypes that provide unique benefits to countermeasure development include enhanced pathogenicity, evasion of vaccines, and evasion of therapeutics. For several other potential benefits of GOF studies involving seasonal influenza, either the potential benefit is long term, or alternative approaches may yield the

same or similar benefits. Interestingly, few unique benefits pertaining to GOF studies involving pandemic influenza were identified. There are several types of GOF studies that entail generating avian influenza strains with phenotypes that may be valuable for surveillance and preparedness efforts, although other advances are needed to fully realize such benefits. This point is controversial, with strong proponents and critics. Additionally, a variety of benefits of GOF studies were identified that may also be provided to some extent by alternative approaches. It should be noted that no attempt was made to provide a probability assessment based on historical data for potential benefits; hence no direct comparison of risk to benefit for a proposed research project is possible.

4.2. Consideration of Ethical Values

The RBA provides information about the potential risks and benefits associated with conducting GOF research, however, determinations about whether such studies should be undertaken involve value judgments based on weighing the risks and benefits. The NSABB identified a number of values that are applicable to the decisions about whether to fund certain GOF studies and how to oversee them. Sources of these values include the Belmont Report,[13] the literature on public health ethics,[14] and the literature on oversight of emerging technologies,[15] as well as the literature specifically debating appropriate approaches to overseeing dual use research of concern (DURC) and GOF research that has raised concerns.[16,17,18,19,20] The commissioned ethics analysis conducted by Dr. Michael Selgelid describes additional values as well as decision-making frameworks to be considered.[21]

Substantive values

The following values are important to consider when determining whether to fund a research proposal involving GOF studies that might entail significant risks.

Non-maleficence: not causing harm. There are inherent risks associated with research involving pathogens that could result in harm to individuals as a result of accidental or intentional infection

with the pathogen. These might include: causing disease; loss of lives; damage to the economy, national or international security, or agriculture; or loss of public trust in science or governance structures. Approaches aimed at preventing harm and mitigating potential risks should be considered and applied to the design, conduct, and communication of GOF research involving pathogens.

Beneficence: promoting beneficial outcomes while preventing harmful outcomes; appropriately balancing benefits and risks; formulating policy that maximizes public benefit while minimizing public harm. Benefits might include: preventing disease; saving lives; improving public health; enhancing the economy, national and international security, or public trust in science and governance structures. When the ultimate goals of the research are to improve public health, public health ethics would consider how effective the research is likely to be in achieving those goals, what the known or potential burdens of the research are, whether those burdens can be minimized, whether there are alternative approaches that are less risky or burdensome, and how the potential benefits and burdens of the research can be fairly balanced. The work of the Presidential Commission for the Study of Bioethical Issues (Bioethics Commission) suggests that those formulating and implementing government policy on scientific research and emerging technologies have a duty of public beneficence – a duty "to promote individual activities and institutional practices...that have great potential to improve the public's well-being," while being "vigilant about risks and harms, [and] standing ready to revise policies that pursue potential benefits with insufficient caution."[22] Both risks and benefits have associated probabilities, magnitudes, and uncertainties. In some instances, it may be justifiable to pursue benefits despite the potential risks; in others, the potential benefits may be foregone due to possible risks.

Social justice: distributing potential benefits and harms fairly (distributive justice) and selecting participants in research fairly, as well as those who may potentially be exposed to risk. There are many different approaches to social justice, such as egalitarianism, utilitarianism, and libertarianism,[23] to name a few. Decisions about whether to fund research that entails some risk should consider how the risks and benefits associated with conducting that research will be distributed, with an effort to distribute risks and benefits as fairly as possible. When considering pandemic potential, fair distribution of risks and benefits must be considered on a global scale.

Respect for persons: allowing competent individuals to make informed choices, and ensuring that the representatives of individuals lacking capacity to choose can make choices in keeping with the wishes, values, or interests of those represented. Autonomy generally requires informing human research participants, laboratory workers, and the public about the risks of research and eliciting their free and uncoerced decision about whether to subject themselves to those risks. In the case of the public, mechanisms for representative decision-making and publicly accountable governance may be needed, as getting consent directly from the members of the public may be impracticable.

[23] Nozick, R., *Anarchy, State, and Utopia*. New York: Basic Books, 1974.

Scientific freedom: avoiding unnecessary interference with scientific research, debate, or publication. Scientific freedom includes an entitlement to avoid interference unless necessary (negative freedom), but not the affirmative right to receive funding or other forms of support for a particular project (positive freedom). Scientific freedom implies a duty of compliance with norms and regulation to promote the responsible conduct of research and protect participants in research and the public. As a corollary to the principle of scientific or intellectual freedom, the Bioethics Commission endorses a principle of regulatory parsimony, requiring "only as much oversight as is truly necessary to ensure justice, fairness, security, and safety while pursuing the public good."[24]

Responsible stewardship: acting in a way that shows concern for children, future generations, and the environment. The Bioethics Commission emphasizes that this is both a domestic and global responsibility that requires "prudent vigilance, establishing processes for assessing likely benefits along with assessing safety and security risks both before and after projects are undertaken."[25]

Procedural Values

The following values apply to the process of decision-making about GOF research and are important to consider when establishing mechanisms to review and/or approve the funding of research proposals involving GOF studies that may entail significant risks.

Public participation & democratic deliberation: making decisions with participation from the public, utilizing respectful debate and inclusive deliberation. Life sciences research is largely a publicly-supported endeavor; therefore, those who allocate funds and conduct life sciences research have a responsibility to be good stewards of public funds and to respond to the interests and concerns of the public. Many, if not all, members of society have a stake in the research enterprise and will be affected directly or indirectly by the benefits and risks stemming from such research. This stakeholder community has diverse values and tolerances for risk, which are important to consider when making decisions about funding and overseeing life sciences research. Some forms of public participation include: oversight by the legislative or executive branches of government, public membership and input on government science advisory committees, other mechanisms of public governance, surveys of public opinion on science policy issues, research models such as community-based participatory research, and efforts by scientists and government officials to share information with the public and better understand the public's interests and concerns. The Bioethics Commission urges the importance of democratic deliberation, as "[a]n inclusive process of deliberation, informed by relevant facts and sensitive to ethical concerns, promotes an atmosphere for debate and decision making that looks for common ground wherever possible and seeks to cultivate mutual respect where irreconcilable differences remain."[26]

[25] Ibid., p5.
[26] Ibid., p5.

Accountability: taking responsibility for one's actions and being prepared to justify or explain them to others. It is important that decisions to fund research are justifiable to the public and others. Decisions should be justified in terms of substantive and procedural values.

Transparency: sharing with the public the information and assumptions used to make decisions, including uncertainties, controversies, and limitations of analyses. Transparency is an important part of accountability and public participation. It also allows review and reconsideration of policy over time as new facts emerge and analysis evolves.

4.3. Decision-Making Strategies and Frameworks for Evaluating and Managing Risks and Developing Policy

The NSABB identified a number of approaches or frameworks that may be used to guide the making of complex decisions with ethical implications, particularly in the face of uncertainty. These may also be used in developing policies for managing GOF research. Different strategies reflect different attitudes toward risk-taking and some may be more appropriate in some situations than others. The NSABB examined a number of such strategies as it attempted to determine the best option(s) with respect to GOF research that has raised concerns. These options are not mutually exclusive, and elements from more than one may be used together to develop a path forward. The following are decision-making frameworks that were considered.

Maximax: choosing the option with the best possible outcome. Maximax is a relatively simple strategy that focuses on choosing the option with the best possible outcomes. While maximax may be appropriate for making some types of personal choices (e.g. playing games with nothing of value to lose), it may not be appropriate for making science and technology policy decisions because most people would want to take appropriate steps to prevent or mitigate risks regardless of benefits. For GOF studies, use of maximax would involve identifying research with the best possible benefits, regardless of risks.

Maximin: choosing the option with best outcome among the worst possible outcomes. Maximin is a risk-averse approach because it aims to avoid the worst possible outcomes. Maximin is another relatively simple approach, but may present difficulties when applied to making science and technology policy decisions, because it would recommend not developing a new technology if this decision could lead to the worst possible outcome. Since all technologies (and scientific ideas) can conceivably lead to good and bad outcomes, strict adherence to maximin would result in a very cautious approach to science and technology development. For GOF studies, use of maximin would involve identifying studies with risks, and choosing the least risky regardless of benefits.

Expected Utility Theory: choosing the option that maximizes expected utility, where expected utility for a possible outcome = probability x utility. Expected utility theory involves a quantitative balancing of risks and benefits and is inherently a more complex process. Cost-benefit analysis in economics is a form of expected utility theory. A problem with expected utility theory is that sufficient evidence may not always be available to confidently estimate the probabilities involved in

the utility calculus. When this is the case, other approaches may be appropriate. For GOF studies, use of expected utility theory would require quantitatively determining the likelihood of risks and benefits and calculating the resulting utility.

Precautionary approach: involves taking reasonable measures to prevent, minimize, or mitigate risks that are significant and plausible. A measure is "reasonable" if it: 1) appropriately balances the values at stake in the risk management; 2) is proportional to nature of the risk (i.e. greater risks require stronger measures); and 3) is likely to be effective. A risk is "plausible" if there is some scientific evidence that it could occur even if the probability of the risk cannot be confidently estimated. There are many versions of the precautionary principle, including ones that are more or less risk-averse.[27, 28] A precautionary approach, in general, would limit an activity unless the environment, health, or security, are clearly protected. This approach can recognize a potential problem early and prevent harm from occurring but may lead to regulatory burdens or unnecessarily limit activities. This approach might restrict potential GOF research unless the studies are demonstrated to be safe.

Permissive approach: in general, this would allow an activity unless the environment, health, or security, are clearly compromised. This approach may reduce unnecessary regulatory burdens but can result in after-the-fact reaction to harms. This approach might allow certain GOF studies to proceed until they are demonstrated to entail significant risk.

Planned adaptation or risk-based approach: provides a systematic way to deal with managing risks in the face of uncertainty. It involves: 1) preparation to identify the risks and regulatory gaps, including input from a broad range of perspectives; 2) putting measures in place to control risk based on the best information available at the time; 3) systematically gathering data and observing the effects of policies; and 4) updating and revising policies as needed. An example of an adaptive approach is the life cycle approach taken by the Food and Drug Administration when making decisions about whether to approve drugs, when that includes post-market surveillance.[29] For GOF studies, this approach might entail allowing studies that raise concerns to proceed under defined conditions, then evaluating the risk-benefit landscape periodically to determine whether the studies that are permitted should continue, be expanded, or be restricted.

Threshold approach: identifying a risk threshold beyond which, certain studies are given special attention or subject to additional scrutiny or oversight and might preclude certain studies. Implementation would involve defining or describing the studies that would require additional oversight as well as a description of what that oversight would entail. This approach would allow for the identification of studies of concern but might need to be reevaluated if the risk landscape changes and the threshold that was identified is no longer appropriate. For GOF studies, this would

[29] FDA determinations about whether a new drug is safe and effective are complex, address uncertainty, and involve ongoing monitoring to assess risks and benefits and take appropriate post-marketing actions as necessary. See: *Structured Approach to Benefit-Risk Assessment in Drug Regulatory Decision-Making*, 2013.
http://www.fda.gov/downloads/ForIndustry/UserFees/PrescriptionDrugUserFee/UCM329758.pdf

entail identifying the characteristics of studies involving significant risks that may not be adequately managed and then stipulating further oversight or determining that they should not be conducted.

Point-source approach: involves controlling where certain studies are conducted and under what conditions. This approach would centralize certain research activities, restricting them to designated locations or facilities. For GOF studies that raise concerns this might involve requiring that certain studies only be conducted in facilities with certain biocontainment conditions, biosafety practices, and security measures.

The NSABB used ideas from a number of frameworks to inform its findings and deliberations (Sections 5 and 6). The criteria for identifying GOF research of concern (GOFROC) (see Recommendation 1) reflect a threshold approach. The principles for guiding funding decisions for GOFROC include elements from several of the decision frameworks described above. For instance, an explicit call for a risk-benefit analysis (Recommendation 1, Guiding Principle 3) reflects expected utility theory; however, a strictly quantitative calculation is probably not possible. The principles to guide funding decisions that call for risk mitigation and a restriction to laboratories with a demonstrated capacity to safely carry out the studies (Recommendation 1, Guiding Principles 4, 5 and 7) incorporate elements of point-source and precautionary approaches. An adaptive approach was considered particularly attractive and appropriate for policies aimed at providing oversight of GOF research (Recommendation 3).

4.4. Examination of the Current Policy Landscape

Many U.S. government agencies fund life sciences research in furtherance of their specific missions. In general, research supported by the USG is founded on the principle of scientific merit and goals of the funding agency. Multiple complementary layers of oversight are in place to manage laboratory and other risks associated with federally-funded life sciences research. These policies are intended to provide oversight at various points throughout the research life cycle, from research conception to its publication and translation into practice. These policies include a foundation of occupational health and medicine (for laboratory and clinical workers), laboratory biosafety practices, and policies that address biosecurity risks. Below is a description of the oversight policies in place for federally-funded life sciences research involving pathogens, with discussion of whether and how such policies apply to GOF studies. This analysis is illustrated in Figures 2 and 3 and summarized in Appendix B.

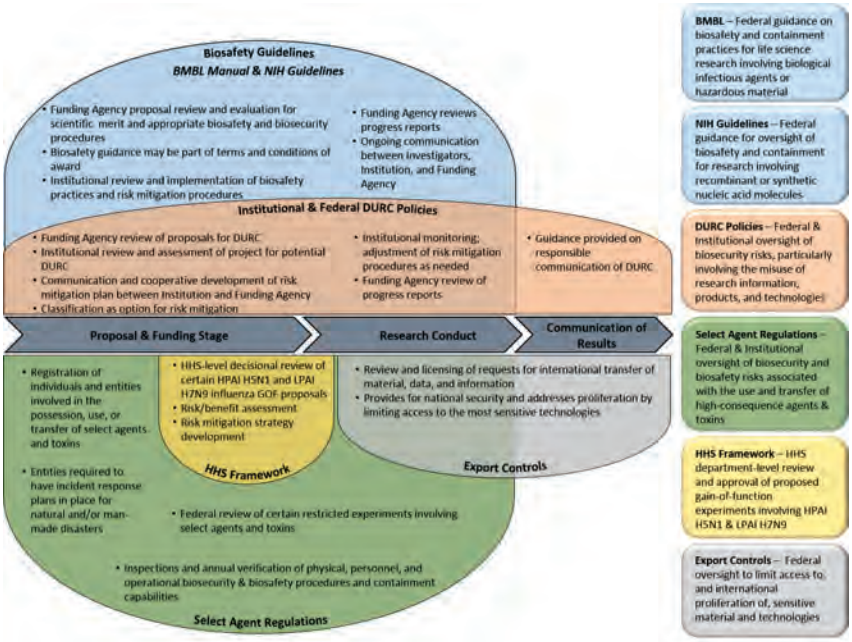

Figure 2. U.S. government oversight of life sciences research involving pathogens. Oversight policies apply at different stages and occur at different levels throughout the research life cycle. See text and Appendix B for descriptions of each policy. These policies have different applicability and scopes and therefore do not apply to all life sciences (or GOF) research projects.

Scientific Merit Review

Departments and agencies within the U.S. government fund diverse portfolios of life sciences research. Funding decisions are based on the scientific merit of a given proposal and the ability of a project to advance the agency's strategic mission. The USG funds life sciences research through a variety of mechanisms including grants, contracts, and cooperative agreements. Each funding agency has its own processes for evaluating research proposals and awarding funds but, in general, proposals are subject to rigorous scientific review by Federal agency staff and often, scientific peers. NIH grant proposals, for example, undergo two levels of review. The first evaluation is by a panel of scientific peer reviewers who score proposals based on scientific merit and other criteria. The second round of review includes discussion of meritorious proposals at public meetings of advisory councils, specific to individual funding institutes and centers within NIH, to determine how proposals fit within their broader strategic objectives.

Biosafety Oversight

Oversight of pathogen research focuses first on ensuring the safe handling of biological agents through appropriate biosafety practices and containment measures, which are addressed by the *Biosafety in Microbiological and Biomedical Laboratories* (*BMBL*)[30], the *NIH Guidelines for Research Involving Recombinant or Synthetic Nucleic Acid Molecules* (*NIH Guidelines*)[31], and other documents. The BMBL and the *NIH Guidelines* provide for federal and institutional biosafety oversight and guidance involving biosafety practices and containment features that are based on risk assessments for specific projects. Such determinations are typically made at the institutional level and are guided by federal guidelines and policies, which are updated as necessary to provide additional guidance for research involving emerging pathogens or technologies. Biosafety is achieved by conducting research under appropriate physical and biological containment levels and employing practices that help to ensure a safe working laboratory environment.

The BMBL is a guidance document developed by CDC and NIH that is generally considered the authoritative reference for laboratory biosafety in the United States. The BMBL provides summary statements for many bacterial, fungal, parasitic, rickettsial, viral, and other agents. These statements describe the characteristics of the pathogen, its natural mode of infection, potential occupational hazards with the agent, and recommendations for laboratory safety and containment. It also describes the fundamentals of biological containment, which include descriptions of proper microbiological practices, safety equipment, and facility safeguards that protect laboratory workers, the environment, and the public from exposure to infectious microorganisms that are handled and stored in the laboratory. It describes the process of biological risk assessment, which enables the appropriate selection of microbiological practices, safety equipment, and facility safeguards that can prevent laboratory-associated infections. It also describes occupational health, immunoprophylaxis, and principles for laboratory biosecurity. The BMBL is updated periodically to refine guidance based on new knowledge and experiences and to address contemporary issues that present new risks that confront laboratory workers and public health.

> **Analysis:** The BMBL does not address GOF studies *per se* but does include summary statements and biocontainment guidance for research involving various influenza strains (including contemporary and non-contemporary human, high and low pathogenic avian, swine, the 1918 influenza strain, and reassortant viruses) and SARS-CoV. MERS-CoV had not emerged at the time of the last BMBL update, but interim laboratory biosafety guidance was issued by CDC.[32]

[31] *NIH Guidelines for Research Involving Recombinant or Synthetic Nucleic Acid Molecules* (NIH Guidelines), November 2013. http://osp.od.nih.gov/sites/default/files/NIH_Guidelines.html

[32] *Interim Laboratory Biosafety Guidelines for Handling and Processing Specimens Associated with Middle East Respiratory Syndrome Coronavirus (MERS-CoV) – Version 2.* http://www.cdc.gov/coronavirus/mers/guidelines-lab-biosafety.html [last updated June 18, 2015]

The BMBL is not a regulatory document. U.S. funding agencies may require it be followed as a term and condition of funding but, in general, compliance with the BMBL is voluntary. In addition, the BMBL provides general biosafety guidance but does not describe detailed procedures or experiment-specific containment protocols.

The *NIH Guidelines* specify the practices for safely constructing and handling: recombinant nucleic acid molecules; synthetic nucleic acid molecules, including those that are chemically or otherwise modified but can base pair with naturally occurring nucleic acid molecules; and cells, organisms, and viruses containing such molecules. The *NIH Guidelines* apply to basic and clinical research involving recombinant or synthetic nucleic acid molecules conducted at or sponsored by institutions that receive NIH funding for any such research. Compliance with the *NIH Guidelines* is required by NIH as a term and condition of award of funding. Other USG agencies may also require compliance with the *NIH Guidelines*.

The *NIH Guidelines* focus on the concepts of risk assessment, risk group classification of agents based on their ability to cause disease in humans and the availability of medical countermeasures, physical and biological containment levels, practices, personal protective equipment, and occupational health. To help ensure the safe conduct of this research, the *NIH Guidelines* specify roles and responsibilities of investigators and institutions. Institutions subject to the *NIH Guidelines* must establish Institutional Biosafety Committees (IBCs) composed of members with appropriate expertise, to review and approve such research. IBCs provide local oversight and ensure compliance with the *NIH Guidelines*. Certain higher risk experiments require review by the Recombinant DNA Advisory Committee (RAC)[33] and specific approval by the NIH Director as Major Actions. These experiments involve the deliberate transfer of a drug resistance trait to microorganisms that are not known to acquire the trait naturally, if such acquisition could compromise the ability to control disease agents in humans, veterinary medicine or agriculture.

In order to continue to provide appropriate guidance for emerging pathogens or experimental approaches, the *NIH Guidelines* are updated periodically. The *NIH Guidelines* have been amended to include additional guidance for work with Risk Group 3 influenza viruses (1918 H1N1, H2N2, highly pathogenic avian influenza (HPAI) H5N1), to specify enhancements to biosafety level 3 containment, practices, and to incorporate occupational health requirements. In 2012, the *NIH Guidelines* were amended again to require further enhancements to facilities, biosafety equipment and practices, including occupational health practices, for research involving HPAI H5N1 strains that are transmissible among mammals by respiratory droplets.

Analysis: The *NIH Guidelines* provide guidance on risk assessment and appropriate containment and practices for conducting research involving recombinant or synthetic nucleic acids, which would

[33] The Recombinant DNA Advisory Committee (RAC) is a federal advisory committee that provides recommendations to the NIH Director related to basic and clinical research involving recombinant or synthetic nucleic acid molecules. See: http://osp.od.nih.gov/office-biotechnology-activities/biomedical-technology-assessment/hgt/rac

apply to most government-funded GOF research. Some IBCs also review and approve non-recombinant pathogen research, however, not all institutions require their IBCs to do so. While the *NIH Guidelines* are often used as a model of biosafety guidance by the broader scientific community, compliance is required only by institutions receiving funding from the NIH for research involving recombinant or synthetic nucleic acid molecules. Therefore, some GOF studies may not be subject to the *NIH Guidelines* depending on whether the institution where the research is being conducted is subject to the *NIH Guidelines*.

The Federal Select Agent Program

The *Public Health Security and Bioterrorism Preparedness and Response Act of 2002*[34] requires the U.S. Departments of Health and Human Services (HHS) and Agriculture (USDA) to establish and regulate a list of select agents — biological agents and toxins that have the potential to pose a severe threat to public health and safety or animal or plant health or animal or plant products. The Federal Select Agent Program (FSAP) is administered jointly by the HHS Centers for Disease Control and Prevention and USDA Animal and Plant Inspection Service. The FSAP oversees the possession, use and transfer of biological select agents and toxins. The Select Agents and Toxins List is reviewed and updated biennially. Under the select agents regulations, individuals and institutions that possess, use, or transfer any select agent are required to be registered, follow appropriate biosafety procedures, and undergo periodic inspections. Individuals must be registered with the FSAP to have access to select agents or toxins, which requires that they undergo a security risk assessment performed by the Federal Bureau of Investigation (FBI). There are legal penalties for failing to comply with the select agent regulations.

In addition to the agents and toxins on the list, the select agent regulations apply to some genetic elements, including nucleic acids that are immediate precursors to infectious forms of any select agent viruses (i.e., complete positive strand RNA viral genomes), as well as some nucleic acids that encode select toxins. Select agent regulations also apply to genetically-modified select agents and toxins. Restricted experiments are described in the regulations and involve the deliberate transfer of or selection for a drug resistance trait to select agents that are not known to acquire the trait naturally. If the acquisition of resistance is to a first-line drug that could compromise the use of the drug to control disease agents in humans, veterinary medicine, or agriculture, the restricted experiment requires special review and approval by the SAP. Some attenuated strains of select agents may be excluded from the regulations based upon a determination that the attenuated strain or modified toxin does not pose a severe threat to public, plant, or animal health or safety. The list of select agents and toxins is reviewed and updated biannually. The Intragovernmental Select Agent and Toxin Technical Advisory Committee serves as an advisory group to the FSAP and provides recommendations on the addition or deletion of agents or toxins to/from the select agent list. Following the disclosure of laboratory incidents at Federal

[34] *Public Health Security and Bioterrorism Preparedness and Response Act of 2002.* https://www.gpo.gov/fdsys/pkg/STATUTE-116/pdf/STATUTE-116-Pg594.pdf

facilities involving select agents in 2014, two advisory committees issued recommendations on ways to strengthen the FSAP.[35, 36] Plans to implement these recommendations are also in place.[37]

Analysis: GOF studies are subject to oversight by the FSAP if they involve pathogens on the select agent list. Researchers and institutions performing such studies must receive favorable security risk assessments by the FBI, register with the FSAP, receive training on the proper procedures and practices for handling such agents, and abide by other aspects of the regulations. SARS-CoV, HPAI H5N1 influenza, and 1918 influenza viruses are select agents. Restricted experiments that would entail conferring antiviral resistance to these viruses would require additional review and approval prior to being conducted. However, MERS-CoV is not a select agent. GOF experiments involving MERS, and other agents not included on the select agent list, would not be subject to oversight by the FSAP (though they could be subject to other federal and institutional biosafety oversight). The FSAP is underpinned by a regulatory requirement that applies to non-USG funded (i.e., private sector funded) pathogen research as well.

Federal and Institutional Oversight of Life Science Dual Use Research of Concern

The U.S. government has issued policies for the oversight of life sciences DURC. These policies focus oversight on research involving 15 high-consequence pathogens and toxins[38] that involve seven categories of experimental activity, which are projects that can be reasonably anticipated to:

1. Enhance the harmful consequences of the agent or toxin;
2. Disrupt immunity or the effectiveness of an immunization against the agent or toxin without clinical or agricultural justification;
3. Confer to the agent or toxin resistance to clinically or agriculturally useful prophylactic or therapeutic interventions against that agent or toxin or facilitates their ability to evade detection methodologies;
4. Increase the stability, transmissibility, or the ability to disseminate the agent or toxin;
5. Alter the host range or tropism of the agent or toxin;
6. Enhance the susceptibility of a host population to the agent or toxin; or
7. Generate or reconstitute an eradicated or extinct agent or toxin listed above.

[35] *Report of the Federal Experts Security Advisory Panel*. U.S. Government, December 2014.
[36] *Fast Track Action Committee Report: Recommendations on the Select Agent Regulations Based on Broad Stakeholder Engagement*, U.S. Government, October 2015.
[37] Lisa Monaco and John Holdren White House Memorandum, October 29, 2015, Next Steps to Enhance Biosafety and Biosecurity in the United States. https://www.whitehouse.gov/sites/default/files/docs/10-2015_biosafety_and_biosecurity_memo.pdf
[38] Section III of the *United States Government Policy for Oversight of Life Sciences Dual Use Research of Concern* and Section 6.2.1 of the *United States Government Policy for Institutional Oversight of Life Sciences Dual Use Research of Concern*. The agents within the scope of the USG DURC policies are the 13 Tier 1 select agents plus HPAI H5N1 and 1918 influenza virus.

Projects involving any of the 15 agents and that could be anticipated to involve any of these seven experimental effects are then determined to be DURC if they then meet the definition of DURC listed in the policy.[39]

The DURC policies outline a coordinated approach to oversight involving the federal funding agencies and institutions that conduct such research. The policy for federal oversight, issued in March 2012, requires Federal Departments and Agencies to review proposed and ongoing research projects to identify any that constitute DURC.[40] The policy for institutional oversight, issued in September 2014, articulates responsibilities of research institutions in identifying and managing DURC. Research institutions are to establish an Institutional Review Entity (IRE) to review research subject to the policy to determine whether any such research involves any of the seven experimental effects, and if so, whether the research constitutes DURC. IREs may review projects not specifically covered under the DURC policies but such additional reviews are voluntary.

When DURC is identified—either by a funding agency or a research institution—the funder and institution are to work collaboratively to develop a risk mitigation plan to help ensure that the research is conducted and communicated in a responsible manner. DURC risk mitigation plans are approved by the federal funding agency and are reviewed on an annual basis by the funder and the institution. Specific risk mitigation measures may be incorporated into a term of award. Risk mitigation may involve modifying the design or conduct of the research in order to address the same scientific question in a manner that poses fewer biosafety or biosecurity risks. Other measures may involve applying enhanced biosafety or biosecurity measures, evaluating the effectiveness of extant medical countermeasures prior to proceeding with particular studies, or establishing a more frequent schedule of DURC reviews to more closely monitor the research as it evolves. It is also expected that a communication plan will be established to ensure that DURC is communicated in a responsible manner. Federal funding agencies can provide advice and guidance on responsible communication, but recommendations on how to communicate research typically are not binding; ultimately, investigators and journal editors decide on how to communicate the research.

> **Analysis:** Some of the seven experimental effects within the scope of the DURC policies could be considered GOF studies. However, GOF studies that involve these effects are only subject to DURC oversight if they involve one of the 15 agents listed in the policies. Only two influenza viruses are within the scope of these policies; SARS and MERS coronaviruses are not. The DURC policies are also inherently subjective. While the list-based approach clearly delineates projects that are subject

[39] The definition of dual use research of concern listed in the *USG Policy for Oversight of Life Science DURC* (USG, March 2012) and the *USG Policy for Institutional Oversight of Life Sciences DURC* (USG, September 2014) is "Life sciences research that, based on current understanding, can be reasonably anticipated to provide knowledge, information, products, or technologies that could be directly misapplied to pose a significant threat with broad potential consequences to public health and safety, agricultural crops and other plants, animals, the environment, materiel, or national security."

[40] The policy for Federal DURC oversight requires Federal funding agencies to compile biannual inventories of projects identified as being subject to DURC oversight. As part of this process, Federal agencies have been identifying projects involving MERS and LPAI H7N9 influenza and proactively managing risks associated with those projects, as necessary.

to oversight, the definition of DURC, and to a lesser extent, the seven experimental effects, all require significant judgment and interpretation.

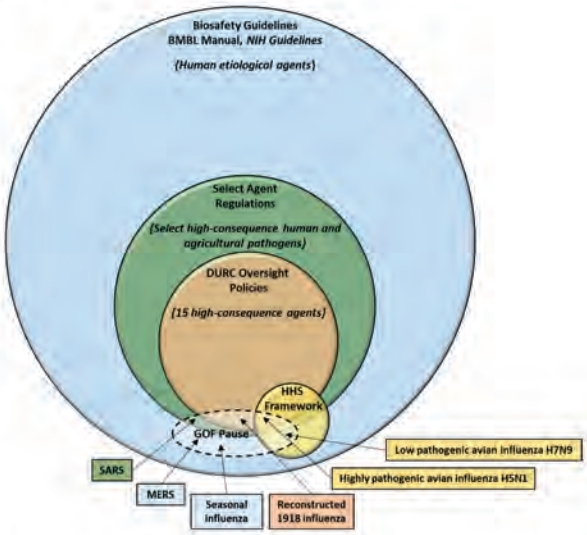

Figure 3. Comparison of the scope of different policies for the oversight of life sciences research involving pathogens. Oversight policies apply to research involving specified agents or procedures. GOF studies involving pathogens or manipulations covered under a given policy would be subject to oversight described by that policy.

Federal-Level Review of Certain Gain-of-Function Studies

The only U.S. policy that specifically addresses GOF studies is the *Framework for Guiding U.S. Department of Health and Human Services Funding Decisions about Research Proposals with the Potential for Generating Highly Pathogenic Avian Influenza H5N1 Viruses that are Transmissible among Mammals by Respiratory Droplets (HHS Framework)*, issued by HHS in February, 2013. Under the *HHS Framework*[41,42] certain proposals with the potential for generating highly pathogenic avian influenza H5N1 viruses that are transmissible among mammals by respiratory droplets receive special review and

[41] *A Framework for Guiding U.S. Department of Health and Human Services Funding Decisions about Research Proposals with the Potential for Generating Highly Pathogenic Avian Influenza H5N1 Viruses that are Transmissible among Mammals by Respiratory Droplets*. U.S. Department of Health and Human Services, February 2013. http://www.phe.gov/s3/dualuse/Documents/funding-hpai-h5n1.pdf

[42] Patterson, A., et al. *A Framework for Decisions about Research with HPAI H5N1 Viruses*. Science. 2013 Mar 1: 339(6123): 1036-1037.

approval before being funded by HHS. This policy was subsequently expanded to include review of similar proposals involving low pathogenic avian influenza H7N9 viruses.[43]

Funding agencies within HHS (including NIH, CDC, and FDA) review relevant proposals for risks and benefits, and refer relevant studies to a Department-level review group, the HHS HPAI H5N1 Gain-of-Function Review Group, for advice prior to funding the proposal. The review group includes a wide range of interdisciplinary expertise from across HHS, and can draw on additional experts within the U.S. government if necessary. HHS reviews GOF research proposals that are subject to the *HHS Framework* and makes recommendations to HHS funding agencies about whether the study is acceptable for funding and whether additional measures may be needed to mitigate risks. HHS considers a number of factors including the following criteria, which must be met in order for a GOF study to be acceptable to receive HHS funding:

1. The virus anticipated to be generated could be produced through a natural evolutionary process;
2. The research addresses a scientific question with high significance to public health;
3. There are no feasible alternative methods to address the same scientific question in a manner that poses less risk than does the proposed approach;
4. Biosafety risks to laboratory workers and the public can be sufficiently mitigated and managed;
5. Biosecurity risks can be sufficiently mitigated and managed;
6. The research information is anticipated to be broadly shared in order to realize its potential benefits to global health; and
7. The research will be supported through funding mechanisms that facilitate appropriate oversight of the conduct and communication of the research

Analysis: The *HHS Framework* requires an explicit consideration of the risks and benefits associated with certain GOF studies prior to making a funding decision. This allows HHS to identify potential risks prior to funding the research and make recommendations about risk mitigation—including consideration of alternative approaches or modifying the experimental design—at the outset. This review process also involves broader expertise including, ethical, legal, security, intelligence, and others. The criteria that must be met in order to receive funding are subject to judgment and interpretation. The scope of the *HHS Framework* is also quite narrow and currently covers only projects involving two influenza viruses and that involve one specific experimental outcome (mammalian transmission by respiratory droplets); other GOF studies involving different pathogens do not receive this pre-funding review.

Reviews under this framework are conducted by a group internal to the U.S. government. Reviewing GOF studies in a confidential setting allows for the examination of potentially sensitive scientific, proprietary, and personal information, and allows for discussions that may be sensitive from a national security or public health preparedness perspective. However, such reviews do not achieve the level of transparency desired by some stakeholders and also make it difficult to independently assess the effectiveness of the review process. Finally, the *HHS Framework* was in

[43] Jaffe, H.W., et al. *Extra Oversight for H7N9 Experiments*. Science. 2013 August 16: 341(6147):713-714.

place for less than two years when the October 2014 funding pause was enacted and only a handful of GOF projects have been reviewed to date, making it difficult to fully evaluate this policy's strengths and limitations.

In response to the funding pause[44], the National Institute for Allergy and Infectious Diseases (NIAID), within the NIH, developed a process for considering on a case-by-case basis studies that might be subject to the GOF pause. Reviews by NIAID include a detailed consideration of the science, including a specific examination of the viral strains in question and specific experiments being proposed. NIAID begins by consulting the investigators and an internal NIAID group determines whether the projects are subject to the pause. When identifying projects subject to the funding pause, NIAID used a fairly broad interpretation of the language set forth in the pause statement and paused, at least initially, more projects than were ultimately determined to meet the scope of the pause policy. NIAID also sought exceptions (using a mechanism provided for in the USG's moratorium statement) for projects that were deemed critical to public health or national security. In determining whether an exception to the pause might be warranted, NIAID considered the intent of the research, the availability of countermeasures, potential alternative approaches, the risks of not conducting the research, and the available mechanisms for ongoing oversight. Exceptions may only be granted by the NIH Director.

Analysis: NIAID's process for identifying GOF projects that are subject to the funding pause is rigorous and serves as an example of federal-level identification and review of GOF studies of potential concern. It includes extensive scientific review and is performed by individuals with experience reviewing projects for DURC potential. It does not involve the same expertise that is provided under *HHS Framework* reviews such as national security, ethics, or legal. Given the limited number of projects that have been examined by NIAID it is difficult to fully evaluate the effectiveness of this approach.

Sharing and Communicating Scientific Findings and Research Products

The majority of life sciences research is conducted in academic settings and the results are communicated openly in scientific journals and public forums. For a small subset of research with national security implications, there are policies in place to restrict access to scientific information or products. Under National Security Decision Directive (NSDD) 189, dissemination of fundamental research is to remain unrestricted to the maximum extent possible and in instances where restriction is necessary for national security, classification is to be the appropriate mechanism for restricting access.[45] Life sciences research that requires classification is classified at its outset and conducted in

[44] *United States Government Gain-of-Function Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS Viruses*. U.S. Government, October 17, 2014. http://www.phe.gov/s3/dualuse/documents/gain-of-function.pdf

[45] NSDD 189 (September 21, 1985) defines fundamental research as "basic and applied research in science and engineering, the results of which ordinarily are published and shared broadly within the scientific community, as distinguished from proprietary research and from industrial development, design, production, and product utilization, the results of which ordinarily are restricted for proprietary or national security reasons." https://research.archives.gov/id/6879779

designated facilities that are equipped with the infrastructure and personnel with appropriate level national security clearances to perform the research. Retroactively classifying research that was conducted in an unclassified setting is immensely challenging and may be unfeasible.

Export controls are federal regulations that regulate exports that have national security or foreign policy implications. Certain materials and information related to biological agents and genetic elements, vaccines, equipment, and related technologies are covered by export control regulations. Furthermore, the transfer of controlled information to a foreign national within the United States may be considered to be an export to that foreign national's country. The regulations are complex but, in general, they specify which items, when being shipped to which destinations, will require an export license. Life sciences research that is openly published is not subject to export controls, but information that is withheld from publication by the investigator or research institution based on security concerns may become subject to export control regulations, and an export license may be required before that information can be shared with foreign nationals. Most biological research activities that are subject to export controls fall under the Department of Commerce's Export Administration Regulations, which control items that have both military and civilian applications.[46] However, some might fall under the jurisdiction of the State Department's International Traffic in Arms Regulations.[47]

A number of scientific journals and families of journals have policies for identifying and reviewing manuscripts that raise biosecurity and biosafety concerns. These efforts are commendable but some have noted the challenges associated with trying to identify DURC or implement risk mitigation measures at the publication stage.[48, 49] NSABB has previously developed strategies and a risk assessment tool to assist in the development of a responsible communication plan for DURC, which might include altering the content, distribution, or timing of a publication.[50] The U.S. government has no authority to mandate redaction, restriction, or classification of a scientific publication that it does not own or control, and efforts to develop a mechanism for restricting communication of unclassified information to only those who require access, remain challenging and to date, unsuccessful.[51]

Analysis: Once a study has been completed, it is difficult to limit the distribution of or access to the findings, particularly if the study was conducted in an open, academic environment. Oversight of DURC, and in particular GOF studies involving pathogens with pandemic potential, may be most

[51] Research information produced under a U.S. government grant is not considered to be owned or controlled by the Federal Government. However, under the Invention Secrecy Act, the U.S. government can nevertheless impose secrecy orders on patent applications if the publication or disclosure of the ensuing patent would be detrimental to national security.

feasible and effective if it occurs 1) upstream (i.e., during the review of proposed studies and before experiments are initiated) and 2) in an ongoing manner while the research is being conducted. Classification may be an option for certain GOF studies, but this would require these studies to be conducted in significantly different settings than they are currently. Further, although certain GOF studies have raised concerns about whether they should be published, it is unlikely that such manuscripts would meet the criteria for classification under U.S. government classification authorities. It is conceivable that certain studies should not be undertaken at all or not published because of unanticipated findings. However, it may be very difficult to predict at the proposal stage whether findings of concern might arise during the experiment, and unanticipated findings that raise concern may be unavoidable. Individual investigators or journal editors have, on security grounds, decided to redact certain material from publication, possibly triggering export controls on the redacted material, but in general such a redaction could not be mandated by the U.S. government.

Broader U.S. Biosafety and Biosecurity Efforts

Parallel to the GOF deliberative process, the USG also initiated broader reviews of biosafety and biosecurity policies and procedures following a series of laboratory incidents occurring at federal institutions in 2014. The Holdren-Monoco memorandum[52] called for federal and non-federal reviews to provide recommendations to strengthen the biosafety and biosecurity practices and oversight system for USG funded research. The memo outlined three immediate actions for U.S. government Departments and Agencies:

1. Conduct a comprehensive review of current biosafety and biosecurity protocols to ensure adequacy and appropriateness for today's infectious disease research
2. Inventory and document culture collections
3. Increase attentiveness throughout research community to ensure the safety of laboratory workers and the American public.

In September 2015, The White House National Security Council tasked the Federal Experts Security Advisory Panel (FESAP) to 1) identify needs and gaps and make recommendations to optimize biosafety, biosecurity, oversight, and inventory management and control for biological select agents and toxins (BSAT); 2) identify actions and any regulatory changes to improve biosafety and biosecurity; and 3) identify an approach to determine the appropriate number of high-containment U.S. laboratories required to possess, use, or transfer BSAT. To obtain broad stakeholder recommendations, the National Science and Technology Council established the Fast Track Action Committee on Select Agent Regulations (FTAC-SAR). In October 2015, USG released the FESAP and FTAC-SAR recommendations[53] that address: the culture of responsibility, oversight, outreach and education; applied biosafety

5. Findings of the NSABB

In developing its findings (Box 2), the NSABB considered the results of the RBA, policy analysis and decision-making frameworks, discussions of ethics, and perspectives of domestic and international stakeholders.

Box 2. Summary of Findings

Finding 1. There are many types of GOF studies and not all of them have the same level of risks. Only a small subset of GOF research—GOF research of concern (GOFROC)—entail risks that are potentially significant enough to warrant additional oversight.

Finding 2. The U.S. government has several policies in place for identifying and managing risks associated with life sciences research. There are several points throughout the research life cycle where, if the policies are implemented effectively, risks can be managed and oversight of GOF research of concern could be implemented.

Finding 3. Oversight policies vary in scope and applicability, and do not cover all potential GOFROC, therefore, current oversight is not sufficient for all GOF research of concern.

Finding 4. An adaptive policy approach is a desirable way to ensure that oversight and risk mitigation measures remain commensurate with the risks associated with the research and that the benefits of the research are being fully realized.

Finding 5. There are life sciences research studies, including possibly some GOF research of concern, that should not be conducted because the potential risks associated with the study are not justified by the potential benefits. Decisions about whether specific GOFROC should be permitted will entail an assessment of the potential risks and anticipated benefits associated with the individual experiment in question. The scientific merit of a study is a central consideration during the review of proposed studies but other considerations, including legal, ethical, public health, and societal values are also important and need to be taken into account.

Finding 6. Managing risks associated with GOF research of concern, like all life sciences research, requires both federal and institutional oversight, awareness and compliance, and a commitment by all stakeholders to safety and security.

Finding 7. Funding and conducting GOF research of concern encompasses many issues that are international in nature.

Finding 1. There are many types of GOF studies and not all of them have the same level of risks. Only a small subset of GOF research—GOF research of concern (GOFROC)—entail risks that are potentially significant enough to warrant additional oversight. As with all life sciences research involving pathogens, GOF studies entail inherent biosafety and biosecurity risks. GOF research involving the generation of pathogens with pandemic potential involves the greatest risks. A laboratory accident involving such a pathogen could potentially release a pathogen that could spread rapidly and efficiently through the human population. A laboratory pathogen with enhanced characteristics could also, if malevolently used, pose a greater threat to national security or public health than similar misuse involving a wild type pathogen. The probability that such events would occur is low but non-zero and the potential consequences are uncertain but potentially significant.

Gryphon's biosafety risk assessment identified studies involving enhanced transmissibility, enhanced pathogenicity, and evasion of immunity as entailing the highest risks for coronaviruses, seasonal influenza, and avian influenza.[55] Manipulations that increase transmissibility, increase pathogenicity, and enable a pathogen to more readily spread through the population have the greatest potential to increase risk; in some strains even a moderate increase might be a concern.

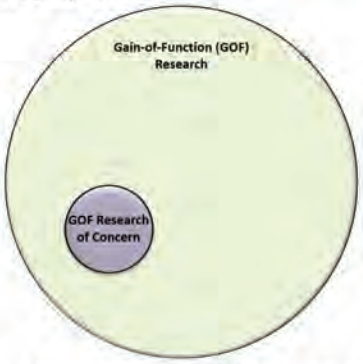

Figure 4. Conceptual categorization of GOF research involving human pathogens. GOF research includes a broad range of experimental approaches, most of which do not raise significant concerns. GOF research of concern represents a small subset of all GOF research that can be reasonably anticipated to result in generation of a pathogen with pandemic potential, described as a pathogen that is likely both highly transmissible and highly virulent in humans.

To help categorize studies based on the level of concern stemming from their associated risks, the NSABB has designated studies as: GOF research and GOF research of concern (GOFROC) (Figure 4). The term "GOF research" would encompass all studies whereby some characteristic of the pathogen is enhanced by experimental manipulation. The vast majority of GOF research does not raise any significant concerns; these studies do not entail novel or significant risks and are subject to appropriate oversight to manage risks. GOF research of concern, or GOFROC, represents the small subset of studies that result in the generation of a pathogen with pandemic potential—that is, a pathogen that is highly virulent and highly transmissible, as judged by its likely ability to spread among human populations (see Recommendation 1 for more thorough descriptions of these attributes).

[55] *Risk and Benefit Analysis of Gain-of-Function Research, Final Report*. Gryphon Scientific, April 2016. http://www.gryphonscientific.com/wp-content/uploads/2016/04/Risk-and-Benefit-Analysis-of-Gain-of-Function-Research-Final-Report.pdf

Finding 2. The U.S. government has several policies in place for identifying and managing risks associated with life sciences research. There are several points throughout the research life cycle where, if the policies are implemented effectively, risks can be managed and oversight of GOF research of concern could be implemented. Federally-funded life sciences research in the U.S. is conducted in accordance with occupational health and safety laws and regulations, the *NIH Guidelines*, the BMBL, policies for the federal and institutional oversight of DURC, the select agent regulations, export control regulations, international treaties and agreements, and other relevant policies. HHS has also developed a framework for guiding funding decisions for certain GOF studies involving H5N1 and H7N9 influenza viruses. Together, these policies aim to mitigate biosafety risks, biosecurity risks, and other risks associated with life sciences research, including many of the GOF studies that have raised concerns.

U.S. policies involve oversight and help manage risks during several phases throughout the research life cycle including the proposal review, the funding decision, during the conduct of the research, and at the time the research is being communicated. There are also numerous entities that are responsible for providing oversight, managing risks or issuing guidance, including funding agencies, federal advisory committees, institutional review and compliance committees, individual investigators, and journal editors.

While effective implementation of these policies can manage much of the risk associated with life sciences research, some GOFROC is more thoroughly monitored than others. Additionally, coverage under current policies is incomplete (e.g., GOFROC funded and conducted by/within the private sector may not be subject to federal oversight). Institutional oversight also varies. For example, IBCs differ in capabilities and expertise, and institutional resources and cultures vary. In addition, there is limited data describing the rate and extent of laboratory accidents, near misses, and security breaches. Little comprehensive data about these critical issues exist, and no entity is currently authorized to collect all of the desirable information that would inform risk-benefit assessments.

Finding 3. Oversight policies vary in scope and applicability, and do not cover all potential GOFROC, therefore, current oversight is not sufficient for all GOF research of concern. U.S. policies are applicable to some but not all GOFROC. Risks associated with GOFROC that does not involve select agents or pathogens subject to oversight under the USG DURC policies or the *HHS Framework*, would largely be managed at the institutional level, in accordance with guidance provided in the *NIH Guidelines* and BMBL. In general, GOFROC that is not conducted with USG funds is not subject to oversight by a federal funding agency.[56] Other countries also fund and conduct life sciences research, including GOF studies, which are beyond the purview of the U.S. government as well.

[56] Research involving a select agent, whose oversight is articulated in Federal statute and requires compliance from all researchers and institutions, would be subject to Federal oversight, regardless of the funding source. Some privately-funded research being conducted at institutions that receive Federal funding for that research may also be subject to oversight under the *NIH Guidelines*, USG DURC policies, or other policies.

In addition, the USG oversight policies vary. Different policies are aimed at managing different risks, and each is implemented by various Federal Departments and Agencies. This can result in redundancies as well as gaps in oversight, as the various policies are not sufficiently harmonized.

Finally, full compliance with policies is essential to their effectiveness. The effectiveness of policies can be enhanced by a commitment to proper implementation and enforcement at the federal, institutional, and individual investigator levels. This can include training, education, codes of conduct, and other mechanisms for continuing to build a culture of responsibility.

Finding 4. An adaptive policy approach is a desirable way to ensure that oversight and risk mitigation measures remain commensurate with the risks associated with the research and that the benefits of the research are being fully realized. Many, but not all, of the policies that apply to GOF studies are adaptive in nature. The BMBL is updated periodically. The *NIH Guidelines* and the select agent programs are updated or revised periodically as well and both have processes for seeking external advice for informing policy development. The DURC policies and the *HHS Framework* do not have articulated mechanisms for reviewing or updating the policies, or for seeking input on policy development (though both state an intention to be updated as necessary).

Great uncertainty is inherent in conducting risk-benefit assessments with currently available data and the uncertainty associated with several key parameters of the risk and benefit assessment made its interpretation challenging. Such uncertainty about risks and benefits may also make risk management difficult. An adaptive policy approach would facilitate refinement of GOF risk management as knowledge and experience are acquired.

Finding 5. There are life sciences research studies, including possibly some GOF research of concern, that should not be conducted because the potential risks associated with the study are not justified by the potential benefits. Decisions about whether specific GOFROC should be permitted will entail an assessment of the potential risks and anticipated benefits associated with the individual experiment in question. The scientific merit of a study is a central consideration during the review of proposed studies but other considerations, including legal, ethical, public health, and societal values are also important and need to be taken into account. Examples of studies that should not be conducted for ethical reasons include those that: involve human subjects who have not been provided and signed an informed consent document approved by an IRB; are anticipated to cause undue harm to a human subject; or that entail risks that are unjustifiable in the light of the benefits. For example, the development of biological weapons is unethical and has been banned by international treaty.[57]

[57] Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction. Signed at London, Moscow and Washington on 10 April 1972; entered into force on 26 March 1975. Depositaries: UK, US and Soviet governments. http://www.opbw.org/

There may be GOFROC that should not be funded on ethical grounds but it is difficult to identify or describe such studies based on general or hypothetical descriptions. An ethical evaluation of a research study would entail an evaluation of the risks and benefits, which requires a thorough understanding of the scientific details of the proposal, including its aims and any foreseeable adverse consequences. In addition, the scientific, public health, and national security landscape is dynamic. Public health needs change as new diseases emerge. Risks may arise or diminish based on the availability (or lack) of effective countermeasures. Benefits may become more or less likely to be realized based on other enabling factors, such as new scientific findings or technologies. Decisions to fund GOF studies must take into account these nuances in the risk-benefit landscape.

The NSABB did not seek to develop a list of studies that should not be conducted but rather sought to develop general principles that describe what is acceptable and not acceptable for funding. A principle-based approach to guiding funding decisions is adaptable and likely more effective. However, one example of a scientific study that should not be conducted might be the insertion of a virulence gene from an unrelated organism into the genome of a virus that is transmissible through the respiratory route, which would be highly unlikely to occur through natural recombination. This study, and others that involve the transfer of virulence genes between disparate microbes would appear to lack public health benefit, since the novel, laboratory-generated pathogen is unlikely to arise naturally and would therefore entail potentially significant and unnecessary risks.

Finding 6. Managing risks associated with GOF research of concern, like all life sciences research, requires both federal and institutional oversight, awareness and compliance, and a commitment by all stakeholders to safety and security. Biosafety and biosecurity risks associated with life sciences research are managed through engineering controls, laboratory practices, medical surveillance and support, appropriate training, and other interventions. However, GOFROC has the potential to generate strains with significant risks that may require additional oversight and containment mechanisms. Managing the risks associated with GOFROC in particular requires a commitment to safety and security at the federal and institutional level that includes a strong foundation of training and a demonstrated commitment to compliance by the research institution, and the individual investigators at the local level.

Finding 7. Funding and conducting GOF research of concern encompasses many issues that are international in nature. The potential risks and benefits associated with GOFROC are international in nature. Laboratory accidents and intentional misuse could have global consequences. The benefits of vaccine and other medical countermeasure development and disease surveillance also have important international implications. The research enterprise is international as well, and GOFROC is being conducted in a number of countries already. While USG funding policy regarding GOFROC only directly affects domestic and international research within the purview of the U.S. government, decisions made by the United States in this area can influence GOFROC oversight policies globally.

Notably, as highlighted during presentations at NSABB and National Academies meetings, GOF research and GOFROC are being conducted in a number of countries and a variety of oversight mechanisms at the national and regional level are in place. In addition, a number of countries and international scientific organizations have been considering issues related to biosafety, biosecurity, dual use research, and GOFROC.[58, 59, 60, 61, 62, 63] International perspectives are important to the development of U.S. policy in this area and global engagement is necessary to foster effective oversight mechanisms and an international culture of responsibility around research involving pathogens.

The U.S. government, often in concert with the NSABB, has been engaged with the international community for many years and continues to work with those governments and organizations actively considering GOFROC-related issues. Presentations to the NSABB, its working groups, and at the National Academies meetings provided perspectives about the activities of foreign governments, international organizations, researchers, and others, and greatly aided the NSABB during the development of this report.

6. Recommendations of the NSABB

Based on its analyses and findings, the NSABB developed the following recommendations (Box 3) to the U.S. government.

Box 3. Summary of Recommendations of the NSABB

Recommendation 1. Research proposals involving GOF research of concern entail significant potential risks and should receive an additional, multidisciplinary review, prior to determining whether they are acceptable for funding. If funded, such projects should be subject to ongoing oversight at the federal and institutional levels.

Recommendation 2. An advisory body that is designed for transparency and public engagement should be utilized as part of the U.S. government's ongoing evaluation of oversight policies for GOF research of concern.

Recommendation 3. The U.S. government should pursue an adaptive policy approach to help ensure that oversight remains commensurate with the risks associated with the GOF research of concern.

- **Recommendation 3.1.** The U.S. government should develop a system to collect and analyze data about laboratory safety incidents, near-misses, and security breaches as well as the effectiveness of mitigation measures to inform GOF research of concern policy development over time.
- **Recommendation 3.2.** The U.S. government should develop or facilitate the development of a system to collect and analyze data about Institutional Review Entity (IRE) challenges, decisions, and lessons learned to provide feedback to the IRE community and to inform policy development for GOF research of concern over time.

Recommendation 4. In general, oversight mechanisms for GOF research of concern should be incorporated into existing policy frameworks when possible.

Recommendation 5. The U.S. government should consider ways to ensure that all GOF research of concern conducted within the U.S. or by U.S. companies be subject to oversight, regardless of funding source.

Recommendation 6. The U.S. government should undertake broad efforts to strengthen laboratory biosafety and biosecurity and, as part of these efforts, seek to raise awareness about the specific issues associated with GOF research of concern.

Recommendation 7. The U.S. government should engage the international community in a dialogue about the oversight and responsible conduct of GOF research of concern.

Recommendation 1. Research proposals involving GOF research of concern entail significant potential risks and should receive an additional, multidisciplinary review, prior to determining whether they are acceptable for funding. If funded, such projects should be subject to ongoing oversight at the federal and institutional levels.

GOFROC entails the generation of pathogens—perhaps novel pathogens—with anticipated pandemic potential. The risks associated with such studies are uncertain but potentially significant. It is possible that generating a laboratory pathogen with pandemic potential introduces a risk of a pandemic, albeit a low probability risk, that did not exist before that pathogen was generated. Therefore, a new, pre-funding review and approval mechanism is warranted before such studies should be undertaken. The NSABB's proposed conceptual approach for guiding funding decisions about GOFROC entails identifying GOFROC and subjecting such studies to an additional pre-funding review and approval process. The attributes that describe GOFROC, the principles that should guide funding decisions for GOFROC, and the steps in a proposed review/approval process for GOFROC are described below.

Identifying GOF research of concern

GOFROC is research that can be reasonably anticipated to generate a pathogen with pandemic potential. Determining whether a proposed research project is likely to do so will entail uncertainty and will require scientific and other expert judgment.

To be considered GOFROC, the research must, in a single step or over the course of multiple manipulations, be reasonably anticipated to generate a pathogen with both of the following attributes:

i. **The pathogen generated is likely highly transmissible and likely capable of wide and uncontrollable spread in human populations.** To be considered "highly transmissible" the pathogen must be judged to have the capacity for sustained secondary transmission among humans, particularly, but not exclusively, by the respiratory route. Such a determination might be informed by data describing human infections by naturally-circulating isolates of the pathogen or studies in relevant experimental mammalian models that serve as a proxy for human infections. To be considered "capable of wide and uncontrollable spread in human populations" it must be judged that there would be limited options for controlling the spread of the pathogen other than patient isolation or quarantine. Such a determination might be made, for instance, if humans lack population immunity to the resulting pathogen, if the pathogen would evade or suppress the human immune response, if the pathogen would be resistant to medical countermeasures, or if existing countermeasures would be unavailable globally in sufficient quantities.

AND

ii. **The pathogen generated is likely highly virulent and likely to cause significant morbidity and/or mortality in humans.** To be considered "highly virulent" the pathogen must be judged to have the capacity for causing significant consequences in humans, such as severe disease and/or a high case fatality rate. Such a determination might be informed by data describing human infections by naturally-circulating strains of the pathogen or studies in relevant experimental mammalian models that serve as a proxy for human disease.

Any study involving the generation of a pathogen exhibiting the two attributes above would be considered GOFROC. However, it is generally anticipated that the following types of activities would not be considered GOFROC:

- Studies to characterize the virulence and transmission properties of circulating pathogens
- Surveillance activities, including sampling and sequencing
- Activities associated with developing and producing vaccines, such as generation of high-growth strains

Importantly, a proposed experiment need not involve the simultaneous enhancement of both phenotypes. Thus, research involving a naturally-occurring pathogen that exhibits one of the above attributes would be considered GOFROC if a study were anticipated to confer the second attribute to the agent (while retaining the first attribute). Other studies may generate a pathogen with the above attributes after a series of manipulations that enhance the phenotypes separately but ultimately result in a pathogen with both attributes. Any route of experimentation that is anticipated to ultimately generate a pathogen that exhibits both of the characteristics above would be considered GOFROC and should be reviewed carefully before it can be funded.

Appendix C describes examples of studies that would and would not be considered GOFROC. These examples are provided as general guidance. A more detailed consideration of the specific characteristics of a pathogen in question as well as the proposed experimental manipulations would be required to determine whether a research proposal is GOFROC.

Pre-funding review and approval of GOF research of concern

Proposals anticipated to involve GOFROC should be subject to additional review prior to making a funding decision and to substantial federal oversight throughout the course of the research, if funded. The NSABB developed principles that should guide the review and funding of these proposals. There should be a high degree of confidence that a study will be conducted in accordance with these principles before determining that the proposal is suitable for funding. Studies that cannot be or are not anticipated to be conducted in accordance with the principles below should not be funded.

Principles for guiding review and funding decisions

Only projects that are in line with **all of the following principles** should be considered acceptable for funding. The principles below are intended to embody the substantive ethical values described in section 4.2 and the process of applying these principles would involve scientific, security, ethical, and other considerations.

i. **The research proposal has been evaluated by a peer-review process and determined to be scientifically meritorious, with high impact on the research field(s) involved.** If GOFROC is to be funded and conducted it must first and foremost address a valuable scientific question or public health need.

ii. **The pathogen that is anticipated to be generated must be judged, based on scientific evidence, to be able to arise by natural processes.** It is difficult to predict the types of pathogens that can or will emerge in nature. Nevertheless, before a pathogen with pandemic potential is generated through laboratory manipulations it is essential to consider whether such a pathogen could arise in nature. GOFROC may be permissible if the study were to generate a pathogen that is anticipated to arise in nature or if the study were to provide insight into natural evolutionary processes. GOFROC would not be permissible if it were to generate a laboratory pathogen that is highly unlikely to arise in nature.

iii. **An assessment of the overall potential risks and benefits associated with the project determines that the potential risks as compared to the potential benefits to society are justified**. Prior to funding GOFROC, the anticipated risks and potential benefits must be carefully evaluated. In general, the potential benefits associated with a research project should be commensurate with or exceed the presumed risks. Projects involving significant risks and little anticipated benefits are ethically unacceptable and should not be funded. If the potential risks appear high, the possible benefits should also appear high. Risks should be managed and should be mitigated whenever possible. The extent to which risks can be mitigated should factor into the assessment.

iv. **There are no feasible, equally efficacious alternative methods to address the same scientific question in a manner that poses less risk than does the proposed approach.** Alternative approaches must be explored and critically examined before funding GOFROC. It is possible that the proposed experimental approach that raises concern is the only feasible approach for addressing the scientific question at hand. In other cases, modifications of the experimental design, use of attenuated or other strains that pose fewer risks to humans, or different approaches with less risk that may provide the same information may be feasible. Lines of experimentation that entail less risk should be pursued whenever possible.

v. **The investigator and institution proposing the research have the demonstrated capacity and commitment to conduct it safely and securely, and have the ability to respond rapidly and adequately to laboratory accidents and security breaches.** Prior to funding, the risks associated with proposed GOFROC must be identified and assessed, and clear, realistic plans for managing risks should be developed. In order to manage risks associated with GOFROC, an institution must have adequate facilities, resources, security, trained personnel, administrative structures, ongoing occupational health and safety monitoring procedures,

relationships with local public health authorities and first responders, and the ability to adapt to unanticipated situations by increasing containment or adding additional safety or security features. In addition to adhering to standards of compliance, an institution (and the investigators proposing the study) should have a demonstrated commitment to laboratory safety and security, scientific integrity, and the responsible conduct of research. The researchers and institution should be committed to a culture of responsibility, perhaps demonstrated through adherence to a formal code of conduct or other measures.

vi. **The results of the research are anticipated to be broadly shared in compliance with applicable laws and regulations in order to realize their potential benefits to global health.** Prior to funding GOFROC, consideration should be given to the type of research-related information and products that are likely to be generated. The research-related information and products are expected to be shared appropriately and a responsible communication plan should be developed at the outset, as appropriate. NSABB[64] and the U.S. government[65] have issued guidance for developing communication plans for dual use research of concern that include consideration of the content, timing, and distribution of the research information.

vii. **The research will be supported through funding mechanisms that allow for appropriate management of risks and ongoing federal and institutional oversight of all aspects of the research throughout the course of the project.** GOFROC should be funded through mechanisms that ensure appropriate biocontainment conditions are utilized, adequate biosecurity precautions are in place, and that the data and materials generated will be shared appropriately. The funding mechanism should allow for modification of required mitigation and oversight features, as well as research objectives during the course of the research, if needed.

viii. **The proposed research is ethically justifiable.** Determinations of whether proposed GOFROC should be undertaken involve value judgments to assess whether any potential risks are justified. Non-maleficence, beneficence, justice, respect for persons, scientific freedom, and responsible stewardship are among the values that should be considered when ultimately making decisions about whether to fund GOFROC.

---

[64] Appendix 5, *Proposed Framework for the Oversight of Dual Use Research Life Sciences Research: Strategies for Minimizing the Potential Misuse of Research Information*. National Science Advisory Board for Biosecurity, June 2007.

[65] Section E, *Tools for the Identification, Assessment, Management, and Responsible Communication of Dual Use Research of Concern: A Companion Guide to the United States Government Policies for Oversight of Life Sciences Dual Use Research of Concern.* U.S. government, September 2014.

The Review Process for Proposals Involving GOF Research of Concern

The NSABB proposes the following conceptual approach for guiding funding decisions about GOFROC (Figure 5). Review of research projects that may involve GOFROC would involve five steps:

1. Investigators and research institutions identify proposed GOFROC, as described by the two attributes for identifying GOFROC.
2. Funding agencies identify or confirm proposed GOFROC.
3. A Department-level panel of U.S. government experts reviews proposals involving GOFROC to determine whether the proposal meets the 8 principles for guiding funding decisions and to make recommendations as to whether the proposed research is acceptable for funding.
4. Funding agencies make a funding decision, and if the proposal is funded, establish risk mitigation plans and issue the funding award with appropriate terms and conditions to help ensure ongoing oversight.
5. Investigators and institutions conduct the research in accordance with any applicable federal, state, and local oversight policies and employ any necessary additional mitigation strategies. Federal agencies provide oversight to ensure adherence to established risk mitigation plans and funding terms.

Investigators and institutions identify GOFROC (Step 1). Prior to submission of an application for funding, investigators and research institutions should identify possible GOFROC and submit with the research proposal any relevant information such as plans for biosafety, biosecurity, and coordination with local and/or state public health and safety officials in the event of an accident or theft; descriptions of facilities available; a justification for the proposed approach that considers possible non-GOFROC alternatives that have been considered; and a discussion of the value and potential benefits of the proposed research. Identification of possible GOFROC should not affect a subsequent federal scientific merit review either positively or negatively.

> **A need for guidance to investigators and institutions.** The U.S. government should develop a "Points to Consider" document to provide guidance to investigators and institutions when preparing research proposals that may involve GOFROC. Such a document would describe any requirements for proposals involving GOFROC and provide guidance on the type of information that should be included in a proposal to facilitate its review. This document should be reviewed and updated as necessary.

Agency and Department-level review of GOFROC (Step 2 & 3). After the standard funding agency scientific merit review process, proposals that are determined to be scientifically meritorious and likely to be favorably considered for funding would also be reviewed by the funding agency (Step 2) to determine if they constitute GOFROC. Prior to being determined acceptable for funding, proposals identified by a funding agency as involving GOFROC would require an additional, higher level, Departmental review (Step 3). If a proposal does not involve GOFROC, it would proceed along the normal pathway for further evaluation and funding decisions.

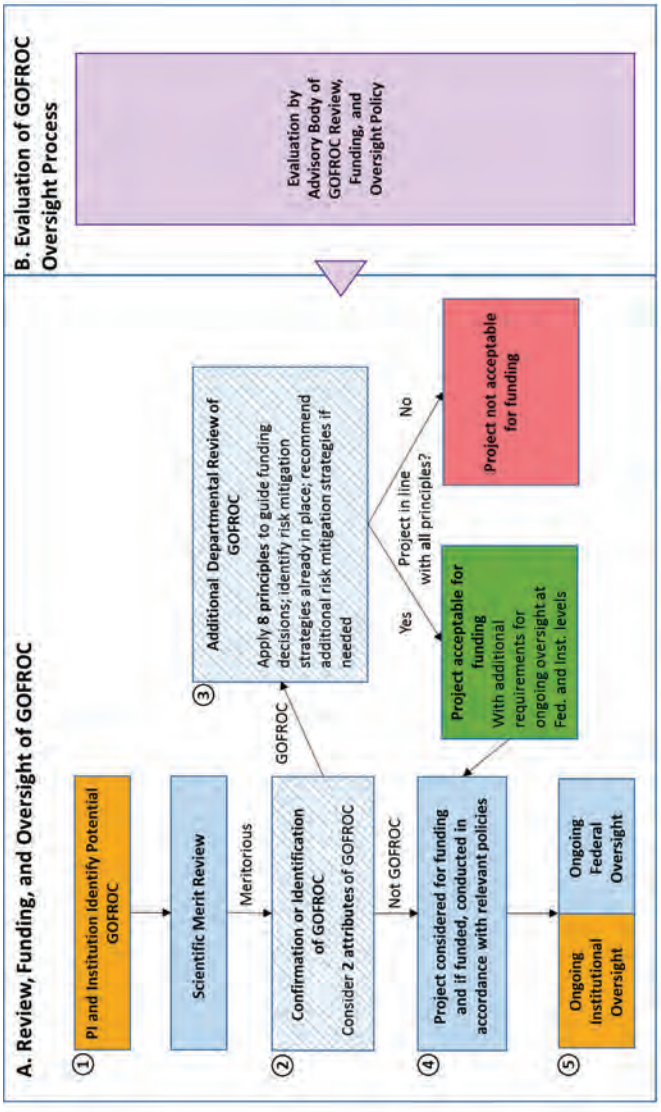

Figure 5. Proposed approach for the oversight of GOF research of concern. A) A conceptual approach for the identification, review, funding, and ongoing oversight of GOF research of concern. B) A Federally-appointed advisory committee would periodically evaluate the policies and processes developed for funding and providing oversight for GOFROC.

The additional review of proposals involving GOFROC would determine whether the proposed research aligns with the 8 principles to guide funding decisions. Applying these principles will help to ensure that the GOFROC is scientifically and ethically acceptable, that the risk-benefit balance is favorable, that alternative approaches are explicitly considered, and that the research can be performed safely and securely. It is envisioned that the additional review of proposals involving GOFROC would involve diverse, multidisciplinary expertise including scientific, public health, biosafety, national security and intelligence, legal, bioethics, and other perspectives. To the extent possible, the Departmental review process should be efficient, well-documented, and adaptive. In addition, the process should be structured to avoid real or apparent conflicts of interest and to provide consistency across USG agencies that might fund GOFROC. It is also envisioned that research institutions proposing the GOFROC might be asked for, and would have an opportunity to provide, any additional information that might be necessary for a thorough and substantive review of the research proposal. The NSABB also recommends (see Recommendation 2) that an advisory body that is designed for transparency play a role in the evaluation of the oversight policies for GOFROC.

Funding decision and risk mitigation (Step 4). During the course of the Department-level review, the relevant risk management plans should be critically evaluated and additional risk mitigation measures may be recommended in order for GOFROC to be considered acceptable for funding. A satisfactory risk management plan would entail appropriate biocontainment facilities and biosafety practices, appropriate standard operating procedures and administrative controls, occupational health and safety programs and security systems for protecting laboratory strains and reagents, and promoting personnel reliability. Some or all of the additional risk mitigation measures listed in Box 4 may also be recommended. Section 6.3 in Gryphon's RBA report also describe additional safety measures that many laboratories performing GOFROC have employed. These and a variety of additional measures could be required as conditions of funding.

Box 4. Additional risk mitigation measures to be employed, as appropriate, for GOF research of concern.

Risk mitigation features that should be considered prior to funding GOFROC include requirements to:

- Provide additional training to researchers
- Enhance biosafety practices or features, as warranted given the specific strains and proposed manipulations
- Enhance security measures around strains, reagents, notebooks, and personnel
- Prohibit certain additional GOFROC experiments without prior approval
- Treat the research as if subject to the USG DURC policies, if it is not already
- Conduct more frequent institutional biosafety and biosecurity reviews of the research
- Require more frequent progress reports and discussions with federal funding agency staff, particularly about unanticipated results that may raise concerns
- Conduct periodic site inspections/evaluations, if not already required
- Identify certain experimental outcomes that would trigger a re-evaluation of the risks and benefits prior to proceeding with a study
- Develop a responsible communication plan, specifically, including a description of biosafety and biosecurity practices that were employed for the research
- Communicate regularly and coordinate with federal, state, and local public health and safety officials on accident and theft response
- Conduct bioethics consultations at the local and federal level throughout the life cycle of the research
- Develop and/or adhere to an appropriate code of conduct

Ongoing oversight (Step 5). Finally, throughout the course of the funding, both federal and institutional oversight are critically important. The project should be carefully monitored to ensure that required conditions are met, that the principles guiding the decision to fund are still satisfied, and that any changes, significant developments, and publication/communication plans are discussed and addressed in a timely manner.

Recommendation 2. An advisory body that is designed for transparency and public engagement should be utilized as part of the U.S. government's ongoing evaluation of oversight policies for GOF research of concern. An advisory mechanism, such as a committee governed by the Federal Advisory

Committee Act[66], would allow for an independent examination of the U.S. government's policies for reviewing, funding, and conducting GOFROC (Figure 5.B.). Such a group could evaluate the additional review and funding processes for GOFROC to understand how decisions were made, identify challenges to implementing the policy, and provide recommendations, as needed. Importantly, this mechanism would also provide transparency, promote public engagement, and would facilitate continued dialogue about GOFROC.

Recommendation 3. The U.S. government should pursue an adaptive policy approach to help ensure that oversight remains commensurate with the risks associated with the GOF research of concern. The risk/benefit profile for GOFROC may change over time and should be re-evaluated periodically to ensure that the risks associated with such research are adequately managed and the benefits are being realized. An adaptive approach to the oversight of GOFROC would entail the continual evaluation of the risks and benefits associated with the research, as well as the burdens and effectiveness of the additional proposal review process and ongoing oversight measures. An adaptive approach would allow policymakers to learn from experience and update policies accordingly as the risk/benefit landscape changes. For instance, the risks associated with a research proposal or project may change if newly developed countermeasures become available or if new information emerges to clarify certain risks or enable certain benefits.

Recommendation 3.1. The U.S. government should develop a system to collect and analyze data about laboratory safety incidents, near-misses, and security breaches as well as the effectiveness of mitigation measures to inform GOF research of concern policy development over time. Examining such data would provide a better understanding of the risks, inform future risk assessments, and allow for the refinement of oversight policies over time.

Recommendation 3.2. The U.S. government should develop or facilitate the development of a system to collect and analyze data about Institutional Review Entity (IRE) challenges, decisions, and lessons learned to provide feedback to the IRE community and to inform policy development for GOF research of concern over time. Examining such data would provide a better understanding of the effectiveness and consistency of policy implementation and support local IRE decision-making.

Recommendation 4. In general, oversight mechanisms for GOF research of concern should be incorporated into existing policy frameworks when possible. Any additional oversight of GOFROC should be built into existing mechanisms rather than having the U.S. government develop a novel policy specific to GOFROC. Adapting or harmonizing current policies is preferable to developing entirely new oversight frameworks or wholly new approaches to manage the risks associated with these studies. There are precedents for additional Department-level pre-funding review of certain GOF studies (i.e.

[66] *Federal Advisory Committee Act*. http://www.gsa.gov/portal/content/100916

HHS Framework) as well as mechanisms for higher-level review and approval of certain studies (i.e., Major Actions, under the *NIH Guidelines*; restricted experiments, under the Select Agent Program). There are also mechanisms for continual Federal-level monitoring of biosafety and biosecurity risks for individual projects (i.e., USG Policy for Federal Oversight of DURC, select agent program) and established mechanisms for ongoing institutional oversight (i.e., IREs under the USG Policy for Institutional Oversight of Life Sciences DURC; IBCs under the *NIH Guidelines*). Wherever possible, these mechanisms should be employed to ensure the initial and ongoing oversight of GOFROC.

Importantly, not all GOFROC would necessarily be subject to the entire suite of U.S. oversight policies. For instance, some studies involving pathogens not included in the USG policies for DURC oversight or not on the select agent list could generate a pathogen with pandemic potential. Additional oversight measures may need to be stipulated at the time of funding for GOFROC proposals that are not subject to sufficient existing oversight. For instance, specific, enhanced containment practices may be required, or a project may require ongoing monitoring at the federal and institutional levels for its potential to be DURC. Box 4 describes a number of risk mitigation measures for GOFROC that could be implemented, potentially by leveraging existing policy frameworks.

Recommendation 5. The U.S. government should consider ways to ensure that all GOF research of concern conducted within the U.S. or by U.S. companies be subject to oversight, regardless of funding source. GOFROC conducted in the U. S. that is funded by the U.S. government or through private funding sources should be subject to equivalent oversight to ensure that the associated risks are adequately managed. The USG should consider ways to introduce oversight not only as a term and condition of a funding award but also via other mechanisms that would enable oversight of all relevant research activities, regardless of the funding source.

Recommendation 6. The U.S. government should undertake broad efforts to strengthen laboratory biosafety and biosecurity and, as part of these efforts, seek to raise awareness about the specific issues associated with GOF research of concern. Current discussions about GOFROC relate to broader domestic and international discussions about laboratory safety and security. A "top down" approach to managing the risks associated with GOFROC through federal policies and oversight is appropriate. However, top-down approaches alone, in the form of federal and/or institutional policies and leadership, will likely not be sufficient. It is also critical to have adequately trained personnel that value safe and secure laboratory environments for conducting GOFROC. Therefore, it will also be important to facilitate a "bottom up" approach whereby scientific leaders and professional societies, as well as research staff involved in the design and conduct of GOFROC, are educated about biosafety, biosecurity, and the responsible conduct of their research. The U.S. government should engage the research community with the goal of promoting a culture of responsibility, or "scientific citizenship," whereby all participants in the research enterprise have a sense of shared responsibility. Such a culture would

incorporate and stress the values of safety, security, compliance, and bioethics, and would work to promote public trust in the scientific enterprise.

Recommendation 7. The U.S. government should engage the international community in dialogue about the oversight and responsible conduct of GOF research of concern. Life sciences research is a global endeavor that continues to grow as more countries invest in their research capacities and as scientists move and collaborate across national boundaries. Life sciences research enables biomedical breakthroughs, pandemic preparedness, public health response efforts for emerging infectious diseases, and also provides an important economic driver. As more investigators undertake research involving pathogens, however, the associated risks become more likely to have international implications. The risks associated with GOFROC are notably international in nature since laboratory accidents or the deliberate misuse of pathogens with pandemic potential could have global consequences. Laboratories anywhere can undertake GOFROC, and publications in the open scientific literature may enable others to generate pathogens with pandemic potential.

NSABB has benefitted greatly from the extensive input into its deliberations by experts representing foreign governments, international organizations, academia, and others during presentations and comments at its meetings and the National Academies symposia.

The U.S. government should continue to engage the international community on issues related to dual use research, including policies, oversight mechanisms, science, research conduct, biosafety, biosecurity, containment, publication, funding, and bioethics. These issues are important in general and are particularly relevant to GOFROC. The U.S. government's international engagement efforts should seek to promote a global culture of responsibility and enhance the quality, legitimacy and effectiveness of oversight processes.

The U.S. government should build these efforts on the substantial international engagement activities that it and the NSABB have carried out since the NSABB was established. Such efforts have included three international roundtable meetings on dual use research issues, a series of webinars focusing on different global regions, and an international consultative workshop on GOF issues[57]. In addition, the U.S. National Academies and the European Academies Science Advisory Council have been engaged in the recent policy debates involving GOF studies and may be well positioned to continue international dialogue on the issue in coordination with national governments and relevant international organizations. The USG is encouraged to participate in such activities.

[57] Information about these meetings and activities, including agendas, summaries, and archived videocasts, can be found on the NSABB website at: http://osp.od.nih.gov/office-biotechnology-activities/biosecurity/nsabb/nsabb-meetings-and-conferences/international-engagement

7. Appendices

Appendix A. Description of NSABB Deliberations

NSABB Deliberations

The NSABB established two working groups to accomplish the two portions of its charge, which were to result in discrete work products.

- **Deliverable 1.** A report conveying NSABB's advice on the design, development, and conduct of the risk and benefit assessments.
- **Deliverable 2.** A report conveying NSABB's formal recommendations on the conceptual approach to the evaluation of proposed GOF studies.

DELIVERABLE 1: ADVISING ON THE RISK AND BENEFIT ASSESSMENTS

The first NSABB working group was tasked with advising on the design and conduct of the risk and benefit assessments. The group met between December 2014 and April 2015 and was consisted of 13 NSABB voting members as well as non-voting *ex officio* members and other *ad hoc* members from Federal agencies. The group convened by telephone conference calls and held a one-day in-person meeting.

The working group developed a draft *Framework for Conducting Risk and Benefit Assessments of Gain-of-Function Research*, which was presented to the full NSABB and developed further based on input from all Board members. The final framework was approved by the full Board on May 5, 2015 and is included in this report as Appendix H. The recommendations in this framework were intended to inform the NIH as it guided the work of Gryphon Scientific in its risk and benefit assessments of GOF research. The aim of the NSABB's framework was to help generate risk and benefit assessments that would provide information that would allow the NSABB to make sound, evidence-based recommendations.

The NSABB recommended that the RBA focus on studies involving influenza viruses (seasonal strains, as well as high and low pathogenic avian strains) and SARS and MERS coronaviruses. Given that most pandemics are associated with respiratory transmission, pathogens capable of airborne transmission were considered to be of most acute concern. NSABB recognized that the RBA would provide information specific to the pathogens and scenarios that were examined, but intended that the assessments would generate information that could be more broadly interpreted and applied. Thus, NSABB's recommended approach to the assessments was intended to align with the USG's October 2014 statement, which states that while "gain-of-function studies that fall within the scope of research subject to the funding pause will be a starting point for deliberations, the suitability of other types of gain-of-function studies will be discussed."

DELIVERABLE 2: RECOMMENDATIONS ON A CONCEPTUAL APPROACH FOR EVALUATING PROPOSED GOF STUDIES

The second NSABB working group was tasked with developing draft recommendations on the conceptual approach for the evaluation of proposed GOF studies. The group met between June 2015 and May 2016 and consisted of 18 NSABB voting members as well as non-voting *ex officio* members and other *ad hoc* members from Federal agencies; (Appendix F). The group convened by telephone conference calls and met twice in person.

In addition to the working group's primary task of developing draft recommendations, it continued to provide input on the conduct of the risk and benefit assessments. The working group also received periodic status updates on the RBA from NIH and Gryphon, as well as reports on the commissioned ethics analysis by Dr. Michael Selgelid, examined draft work products, and reported back to the full NSABB.

In developing draft recommendations on a conceptual framework for evaluating proposed GOF studies, the working group structured its deliberations into three phases.

Phase I. Policy examination, research, and information gathering
Phase II. Interpretation, analysis, and synthesis of information and results
Phase III. Development of recommendations

In Phase I the working group sought to 1) identify and examine the information necessary to inform development of recommendations and 2) begin to identify principles that should guide the development of NSABB recommendations. The working group began its deliberations by considering the topic areas discussed at the NSABB meeting in May 2015, which included examination of relevant U.S. and international policy and consideration of broader perspectives such as those from funding agencies, national security experts, journal editors and scientific publishers, ethicists, and others. The working group held an in-person meeting to consult with experts on many of these topics. The working group also examined a number of published GOF studies and discussed how current policies might apply to such studies to provide oversight and risk mitigation.

During Phase II the working group focused on translating information about risks and benefits as well as ethics into decisions and recommendations. It examined how current policies apply to GOF studies and began to develop preliminary observations and findings. The working group discussed the ethical issues associated with funding and conducting GOF studies, particularly noting the values and ethical decision-frameworks that might be applied to policy decisions about GOF studies. The working group also developed analytic tools to assist it in systematically analyzing the results of the risk and benefit assessments. In November 2015, the working group began receiving briefings from Gryphon conveying the results of the RBA, as well as reports on ethics from Dr. Selgelid. The group sought to identify GOF

studies that might raise particular concerns and may require additional oversight or consideration prior to being funded.

In Phase III the working group developed its draft recommendations based on its analysis of the risk and benefit assessments and the ethics report, and consideration of all other information and perspectives that were examined.

Deliberations by the Full NSABB

The full NSABB convened times 6 times between October 2014 and May 2016. At these meetings the NSABB working groups provided progress updates and the full Board, deliberated the issues further, consulted with various experts, and sought public feedback. Public comments made at NSABB meetings and delivered to the NSABB in writing were carefully considered by the Board during its deliberations. The articles, resources, and stakeholders consulted by the NSABB and its working groups throughout this process are listed in Appendix E.

On November 25, 2014, NSABB voted to approve a statement conveying to the USG concerns it heard regarding the implementation of the funding pause for certain GOF studies.[68] On May 5, 2015, NSABB voted to approve its *Framework for Conducting Risk and Benefit Assessments of Gain-of-Function Research*.[69] On May 24, 2016, NSABB voted to approve its *Recommendations for the Evaluation and Oversight of Proposed Gain-of-Function Research* (this document).

Role of the National Academies in the Deliberative Process

The National Academies played a critical role in the ongoing deliberative process. The National Research Council and the Institute of Medicine (now National Academy of Medicine) were asked to convene two forums to engage the life sciences community and to solicit feedback from scientists, the public, and other stakeholders. These forums involved discussion of principles important for the design of RBA of GOF research and of NSABB draft recommendations.

The first National Academies workshop was held on December 15 & 16, 2014 and focused on the potential risks and benefits associated with GOF studies, ways to assess risks and benefits, strengths and limitations of risk-benefit analyses, and the ethical and policy implications associated with funding and

[68] *Statement of the National Science Advisory Board for Biosecurity Regarding the USG Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS Viruses*. National Science Advisory Board for Biosecurity, November 25, 2014.
http://osp.od.nih.gov/sites/default/files/resources/Final%20NSABB%20Funding%20Pause%20Statement_12-12-14_0.pdf
[69] *Framework for Conducting Risk and Benefit Assessments of Gain-of-Function Research*. National Science Advisory Board for Biosecurity, May 5, 2015.
http://osp.od.nih.gov/sites/default/files/resources/NSABB_Framework_for_Risk_and_Benefit_Assessments_of_GOF_Research-APPROVED.pdf

conducting GOF studies that have raised concerns.[70] The discussions at this meeting directly informed the development of NSABB recommendations for conducting the RBA and its subsequent deliberations. In particular, the discussions about the potential risks and benefits associated with GOF studies informed NSABB's recommendations for the types of risks and benefits that should be analyzed by Gryphon. A common theme at this National Academies meeting was that the term "gain-of-function" is too broad and that in fact, only a subset of GOF studies truly raise concerns. NSABB applied this insight to its subsequent analysis of the RBA by seeking to identify the subset of GOF studies that raised significant or unique concerns. Finally, the legal and policy discussions that were initiated at this meeting prompted the NSABB to explore these topics, as well as ethical issues, further.

The second National Academies meeting was held on March 10 & 11, 2016 and included a discussion of the completed RBA and NSABB's preliminary findings and draft recommendations. NSABB's proposed attributes for identifying GOFROC were a major discussion point at this meeting, which resulted in NSABB refining and clarifying these attributes. In addition, there was significant discussion about the desirability of an adaptive policy approach, the need for data to inform policy decisions, and the role that a federal advisory committee might play in evaluating GOFROC or GOFROC policy. This meeting also had a significant focus on international issues and perspectives, with specific discussion of ongoing and potential future international activities in this area.[71]

The Risk and Benefit Assessments of GOF Studies

NIH commissioned Gryphon Scientific to perform formal risk and benefit assessments to provide the NSABB with qualitative and quantitative information about the risks and benefits associated with conducting certain GOF studies. Dr. Rocco Casagrande, the principal investigator for the study, presented to the NSABB on May 5, 2015 an overview of Gryphon's approach to conducting the RBA, which included a quantitative biosafety risk assessment, a semi-quantitative biosecurity risk assessment, and a qualitative benefit assessment. Prior to voting to finalize its *Framework for Conducting Risk and Benefit Assessments of Gain-of-Function Research*, NSABB discussed with Dr. Casagrande its draft recommendations and how Gryphon's proposed approach aligned with NSABB's proposed recommendations. In June 2015, Dr. Casagrande presented and discussed a more detailed work plan with the NSABB working group. Over the course of the study, the NSABB working group received occasional progress reports from Gryphon and NIH staff, and were provided draft sections of the RBA as they became available. In November 2015 the NSABB working group began receiving the results of the completed RBA. A draft version of the report was posted in advance of the January 2016 NSABB meeting. Gryphon's final report was made publicly available in April, 2016.[72]

[71] National Academies of Sciences, Engineering, and Medicine. 2016. *Gain of Function Research: Summary of the Second Symposium, March 10-11, 2016*. Washington, DC: The National Academies Press. doi: 10.17226/23484.

[72] *Risk and Benefit Analysis of Gain-of-Function Research, Final Report*. Gryphon Scientific, April 2016. http://www.gryphonscientific.com/wp-content/uploads/2016/04/Risk-and-Benefit-Analysis-of-Gain-of-Function-Research-Final-Report.pdf

The NIH Office of Science Policy managed the contract with Gryphon Scientific. NIH staff met weekly with Gryphon to accomplish the goals of the Statement of Work and to ensure the recommendations provided in the NSABB's *Framework for Conducting Risk and Benefit Assessments of Gain-of-Function Research* continued to inform the conduct of the RBA, as appropriate. NIH staff also consulted with NSABB *ex officio* members to get broader expertise and advice, and to help ensure that the risk and benefit assessments yielded information that would inform subsequent policy deliberations by the U.S. government.

Considering Ethical Issues Associated with GOF Studies

To guide the NSABB's evaluation of the risks and benefits associated with GOF studies and its development of recommendations, the Board sought additional input and analysis on ethics. NIH commissioned Dr. Michael Selgelid, Monash University, to examine the literature regarding the ethical issues associated with funding and conducting GOF research and to explore different ethical frameworks that might be utilized when considering how to evaluate the potential risks and benefits associated with GOF studies. Dr. Selgelid was also asked to provide an ethical decision-making framework that NSABB could consider using when analyzing the information provided in the risk and benefit assessments of GOF studies. The decision framework was to identify and consider ethical values that may not be fully captured by a RBA. Dr. Selgelid's analysis was to be accomplished in a neutral, objective manner, without making any definitive recommendations on whether and how to fund or conduct certain GOF studies or what policy course might be the most appropriate. Dr. Selegelid presented his initial work to the NSABB in September 2015 and delivered to the NIH a draft paper in December 2015, which was conveyed to the NSABB and made publicly available. A final version of the paper was made publicly available in April 2016.[73]

[73] Selgelid, M., *Gain-of-Function Research: Ethical Analysis*. April 2016. http://osp.od.nih.gov/sites/default/files/Gain_of_Function_Research_Ethical_Analysis.pdf

Appendix B. Summary of U.S. Policies for Biosecurity and Biosecurity Oversight

Oversight Measures	Risks Addressed	Description of Oversight	Analysis/Applicability to GOF Studies
Biosafety in Microbiological and Biomedical Laboratories (BMBL), 5th Edition (December 2009) http://www.cdc.gov/biosafety/publications/bmbl5/index.htm	Biosafety risks	**Applies to:** Life sciences research involving infectious microorganisms or hazardous biological materials **Description:** General biosafety practices and biological containment for various classifications (risk groups) of microorganisms and etiological agents	BMBL does not describe GOF studies per se but does include summary statements and biocontainment guidance for research involving various influenza strains (including contemporary and non-contemporary human, high and low pathogenic avian, swine, the 1918 influenza strain, and reassortant viruses) and SARS-CoV. MERS-CoV had not emerged at the time of the last BMBL update but interim laboratory biosafety guidance was issued by CDC and is referenced by BMBL. BMBL is a guidance document and generally considered the authoritative reference for laboratory biosafety but it is not a regulatory document; compliance is voluntary.
NIH Guidelines for Research Involving Recombinant or Synthetic Nucleic Acid Molecules (November 2013) http://osp.od.nih.gov/office-biotechnology-activities/biosafety/nih-guidelines	Biosafety risks	**Applies to:** Basic or clinical life sciences research that involves recombinant or synthetic nucleic acid molecules and is conducted at an institution receiving NIH funding for any such research **Description:** Describes roles and responsibilities of institutions and investigators in safely conducting research. Requires institutional review with a focus on the concepts of risk assessment, risk group classification of agents, physical and biological containment levels, practices, personal protective equipment, and occupational health. **Advised by:** NIH Recombinant DNA Advisory Committee (RAC)	The NIH Guidelines have been amended to include additional guidance for work with Risk Group 3 influenza viruses (1918 H1N1, H2N2, highly pathogenic avian influenza (HPAI) H5N1) to specify enhancements to biosafety level 3 containment, practices, and occupational health requirements. NIH Guidelines were amended again to require further enhancements to facilities, biosafety equipment and practices, including occupational health practices, for research involving HPAI H5N1 strains transmissible among mammals by respiratory droplets. NIH Guidelines are often used as a model of biosafety guidance by the broader scientific community but compliance is required only by institutions receiving such funding from the NIH. The scope is also limited to research involving recombinant or synthetic nucleic acids. Some IBCs also review and approve non-recombinant pathogen research; however, not all institutions require their IBCs to do so.
HHS and USDA Select Agent Program (as of July 2014) http://www.selectagents.gov/regulations.html	Biosecurity (physical and personnel) and biosafety risks	**Applies to:** Biological agents and toxins that have the potential to pose a severe threat to public health and safety, based on a set of criteria. **Description:** Regulates the possession, use, and transfer of select agents and toxins. Overseen by the Federal Select Agent Program. Requires registration of individuals and entities; federal background investigations; federal review of restricted experiments; training; institutional compliance; etc. **Advised by:** Intragovernmental Select Agents and Toxins Technical Advisory Committee	Studies that could be considered GOF studies, which involve pathogens on the select agent list, are subject to oversight by the SAP. Researchers and institutions performing such studies must receive favorable security risk assessments by the FBI, register with the SAP, receive training on the proper procedures and practices for handling such agents, and abide by other aspects of the regulations. SARS-CoV, HPAI H5N1 influenza, and 1918 influenza viruses are select agents and GOF studies involving these pathogens are subject to oversight by the SAP. Restricted experiments that would entail conferring antiviral resistance to these viruses would require additional review and approval prior to being conducted. GOF experiments involving MERS, and other agents not included on the select agent list, would not be subject to oversight by the SAP.

USG Policy for Federal Oversight of DURC (March 2012) http://www.phe.gov/s3/dualuse/Pages/USGOversightPolicy.aspx	Biosecurity risks, particularly involving misuse of research information, products, and technologies (DURC)	**Applies to:** Life sciences research conducted at an institution receiving USG funding that involves any of 15 agents that pose the greatest risk of deliberate misuse with most significant potential for mass casualties or devastating effects.	The federal DURC policy requires identification and oversight of certain pathogen research involving 7 experimental types, some of which can be described as GOF experiments (i.e., enhancing the harmful consequences of an agent; increase transmissibility; alter host range; etc.) by Federal funding agencies. DURC policies only apply to research involving 15 pathogens. Institutions may review other studies for DURC potential but are not required to do so. Certain GOF studies that involve other agents would not be subject to DURC oversight under the policies.
USG Policy for Institutional Oversight of DURC (September 2014) http://www.phe.gov/s3/dualuse/Pages/InstitutionalOversight.aspx	Biosecurity risks, particularly involving misuse of research information, products, and technologies (DURC)	**Applies to:** Life sciences research conducted at an institution receiving USG funding that involves any of 15 agents that pose the greatest risk of deliberate misuse with most significant potential for mass casualties or devastating effects.	The institutional DURC policy requires federally-funded institutions to establish a system for the identification and oversight of certain pathogen research involving 7 experimental types, some of which can be described as GOF experiments (i.e., enhancing the harmful consequences of an agent; increase transmissibility; alter host range; etc.) DURC policies only apply to research involving 15 pathogens. Institutions may review other studies for DURC potential but are not required to do so. Certain GOF studies that involve other agents would not be subject to DURC oversight under the policies.
HHS Funding Framework for GOF studies (August 2013) http://www.phe.gov/s3/dualuse/Pages/HHSh5n1Framework.aspx	Biosafety and biosecurity risks associated with certain GOF experiments involving agents with pandemic potential	**Applies to:** Gain-of-function studies that are reasonably anticipated to generate HPAI H5N1 viruses that are transmissible, and LPAI H7N9 viruses that have increased transmissibility, between mammals by respiratory droplets **Description:** Describes an HHS Department-level review pre-funding review and approval process for certain GOF studies, which can result in funding, not funding, or funding with certain conditions and ongoing oversight.	The only policy focused specifically on funding decisions related to the types of GOF studies that have raised concerns. Narrowly focused only on specific GOF studies (enhancing mammalian transmissibility) on two avian influenza viruses; other GOF studies may raise concern and would not be reviewed under this framework.
USG Export Control Regulations http://www.bis.doc.gov/index.php/regulations/export-administration-regulations-ear		**Applies to:** Export or release of equipment, software and technology, chemicals, microorganisms, toxins, and other materials and information deemed dual use or strategically important to U.S. national security, economic, and/or foreign policy interests	Comprehensive set of federal regulations that control and restrict the export and release of sensitive equipment, software and technology; chemical, biological, and other materials and information as a means to promote national security interests and foreign policy objectives.

Appendix C. Identifying GOFROC: Examples of Studies that Would and Would Not be Considered GOFROC

Experiment that is anticipated to entail GOFROC and therefore require additional pre-funding review and approval	Rationale (See NSABB Rec. 1 for description of GOFROC Attributes)
An experiment that is anticipated to generate avian influenza viruses that are transmissible by the respiratory route in mammals, if the starting virus is highly virulent in humans.	**Attribute 1.** The experiment is anticipated to increase transmissibility by the respiratory route in a relevant experimental mammalian model. Further, altering the host range from birds to mammals could generate a virus to which there is no existing population immunity, resulting in a virus capable of wide and potentially uncontrollable spread among humans. **Attribute 2.** Since the starting virus is highly virulent in humans it can be reasonably anticipated that the resulting virus will remain highly virulent in humans.
Reassortant studies involving avian and human influenza virus strains conducted to identify reassortants with pandemic potential that could arise naturally.	**Attribute 1.** Given the starting viruses and the goal of the experiment to identify/select for reassortants that are potentially highly transmissible in mammals, it can be reasonably expected that one or more of the resulting strains could be highly transmissible in humans. Since the resulting viruses are reassortants between bird and human influenza viruses, it can be anticipated that the antigenicity of at least some will remain avian-specific such that human populations would not be expected to have been exposed to such a strain or have pre-existing immunity. Therefore, it can be anticipated that a resulting virus could be capable of wide and uncontrollable spread. **Attribute 2.** Whether or not any of the starting viruses are highly virulent in humans, it can be reasonably anticipated that the expression of novel combinations of gene segments, derived from different influenza strains, in reassortant viruses could result in a range of characteristics that includes high virulence.
Studies that would result in a strain of *Yersinia pestis* more likely to cause pneumonic forms of infection and be resistant to antibiotics.	**Attribute 1.** Given the ease of transmission of *Yersinia pestis* in previous pandemics, manipulations that would enhance its ability to spread by respiratory droplets and cause pneumonic infections would generate a highly transmissible pathogen. In addition, if this manipulation involved a strain that was resistant to frontline antibiotics, it can be anticipated that there would be limited options for controlling the spread of the pathogen among humans. **Attribute 2.** Since the starting agent is highly virulent in humans, particularly when spread through the respiratory route, it can be reasonably anticipated that the resulting agent will remain highly virulent in humans.

Experiment NOT anticipated to entail GOFROC and therefore not require additional pre-funding review and approval	Rationale
Studies aimed at generating a mouse-adapted MERS-CoV or other emerging human respiratory pathogen	**Not Attribute 1.** The starting virus is transmissible by the respiratory route among humans but is not highly transmissible. MERS-CoV transmission usually occurs as a result of close contact (e.g. providing unprotected care to an infected patient). Sustained community transmission has not been observed. Furthermore, the proposed adaptation to recapitulate human disease symptoms in mice would not be reasonably anticipated to enhance transmissibility thus the resulting virus would not be anticipated to be capable of wide and uncontrollable spread. **Possibly Attribute 2.** The starting virus is already highly virulent in humans and is associated with significant morbidity and mortality. However, it should also be noted that a mouse-adapted strain is likely to be less virulent in humans.
Studies enhancing the growth of seasonal influenza viruses, which may be performed during vaccine production	**Not Attribute 1.** The starting seasonal influenza virus is highly transmissible by the respiratory route in humans however, population immunity is likely to exist against circulating (and recently circulated) strains. Enhancement of growth is unlikely to result in a virus that can evade immunity, thus a virus capable of wide and uncontrollable spread would not be likely. **Possibly attribute 2.** Increasing seasonal virus' ability to replicate could potentially result in its increased ability to cause disease, which could result in highly virulent strains. **Note:** If this experiment were to involve an attenuated strain, as is often the case with vaccine production, it would be unlikely to result in a virus that is highly virulent in humans.
Antigenic drift studies whereby seasonal influenza viruses that are no longer neutralized by vaccine-induced immunity are generated and selected for in the laboratory.	**Not Attribute 1.** The starting seasonal influenza virus is highly transmissible by the respiratory route in humans. However, antigenic drift studies generate influenza viruses with some resistance to a specific immunization but do not change the antigenic character of the virus to a degree such that it would no longer be recognized by the human immune system. Given that the starting virus is a human virus—not one that naturally infects birds or other non-human hosts—there would likely be some pre-existing population immunity to the resulting strains. **Possibly attribute 2.** The experimental manipulation would not be anticipated to increase the virulence of the virus. The resulting strains are likely to exhibit a similar level of virulence as the starting strain. Whether its virulence is considered high or low would depend on the specific initial strain used.

Appendix D. Summaries of Stakeholder Perspectives

The NSABB consulted a wide range of experts and stakeholder groups including not only scientists and institutions that fund and conduct life sciences research, but a much larger and diverse array of groups including public health officials, medical practitioners, emergency responders, vaccine developers, scientific journals, as well as the general public, non-governmental organizations, individuals with international perspectives and others. To accomplish this, NSABB organized meetings with expert presentations and panels that offered opportunities for interested groups there and for individuals and organizations to express their views and contribute throughout the deliberative process in ways that have informed the NSABB deliberations. These include: several public full NSABB advisory committee meetings that included sessions dedicated to obtaining public comment, two public symposia hosted by the National Academies that obtained comments from the public at the meetings and online, as well as comments submitted to the NIH and NSABB by email, and discussions with subject matter experts during NSABB WG conference calls and in-person meetings. Also included below are views expressed in some of the articles that have been published on this topic. A complete list of the individuals consulted and articles examined by NSABB are listed in Appendix E. Gryphon also conducted extensive consultations with experts as part of their risk and benefit assessments of GOF research. Those experts are not listed here but a listing is available in Gryphon's report. [74]

The following is a synthesis of stakeholder ideas and opinions expressed during the deliberative process. Many of these points were conveyed in more than one venue and by more than one person or group.

Scientists and Others Favoring GOF Research

A variety of influenza and coronavirus researchers who conduct GOF research, and other life sciences researchers have stated that GOF studies are widely used and fundamental for understanding viruses, and therefore are crucial to undertake. This group generally favors conducting such research because it aims to benefit society. In their view, such research can be safely conducted under current oversight frameworks and further restrictions will impede valuable work that will lead to important scientific information about these viruses, leading to better drugs and vaccines, as well as to improving the specificity of surveillance, particularly for influenza. In addition, some GOF studies are viewed as essential, specifically those that alter host range or enhance pathogenicity in order to develop animal models of disease (for example, with SARS-CoV) or GOF studies that generate drug or countermeasure resistance, which are important in satisfying various FDA requirements for marketing approval. Those who support GOF studies also point out that such studies are needed for predicting what amino acid changes are important for human transmission and therefore are important for the selection of candidate vaccine viruses. They also argue that GOF studies are important for prioritizing viruses for risk management (surveillance) and that further work will make these applications more robust. These

[74] *Risk and Benefit Analysis of Gain-of-Function Research, Final Report*. Gryphon Scientific, April 2016. http://www.gryphonscientific.com/wp-content/uploads/2016/04/Risk-and-Benefit-Analysis-of-Gain-of-Function-Research-Final-Report.pdf

individuals also pointed to the risks associated with not doing GOF research (generally due to a lack of preparedness for natural public health threats) and argued that they must also be considered.

While acknowledging there are risks associated with GOF research, proponents believe those risks are manageable and have been overstated by some, as evidenced by the fact that laboratory acquired infections are rare and infections in the community as a result of releases from a laboratory are almost unknown. While risk cannot be zero, the work can be conducted safely and securely with appropriate risk mitigation including containment along with good training and with the implementation of robust occupational medicine programs. Alternatives to GOF do not always provide the full answer to key questions and may yield misinformation. Supporters of GOF studies have also expressed concerns about the effects of the current funding pause and possible additional oversight on the field of virology and young researchers, and feel that there are costs of not undertaking the work in question. A major need is for better definition of what is meant by GOF with a clear distinction between GOF studies and GOF studies of concern. Some have suggested that only viruses with increased transmissibility and pathogenicity represent risks that exceed those of other infectious diseases research. They have also noted that SARS and MERS viruses are different from influenza, and require a different risk assessment approach since they are already virulent human pathogens; GOF research is needed to develop animal models that will benefit development of countermeasures for coronaviruses. Some supporters have acknowledged that there may be some experiments that should not be done. Finally, proponents of GOF research have stated that the risks from naturally occurring influenza viruses, which they argue could be reduced through GOF work, are greater than risks from performing GOF studies.

Scientists and Others Critical of GOF Studies

Opponents and critics of GOF research have generally focused their concern on a subset of GOF studies—those that involve enhancing the pathogenicity and/or transmissibility in mammals (particularly by the respiratory route), which may result in the generation of novel pathogens with pandemic potential. Critics have argued that the generation of novel laboratory pathogens with pandemic potential poses major public health risks and some have argued such studies should not be conducted. They have presented and published calculations that suggest a high probability of global outbreaks of influenza that might kill hundreds of millions of people, as a result of the release from a laboratory of a novel GOF virus. There is some disagreement about these estimates and how likely a pandemic might be, but opponents generally argue that even a relatively low probability of a potentially massive outbreak with major consequences is unacceptable. Some critics of GOF studies have acknowledged that there are a number of GOF studies that can and should be conducted.

Opponents of certain GOF studies have also argued that the benefits of GOF studies have been overstated, or are questionable, and that the benefits generally do not outweigh the biosafety risks. They also question claims about the effectiveness of risk mitigation strategies, since human factors and human error are unavoidable and hard to control, and institutional compliance and competence may vary. Critics have disputed the value of GOF studies to surveillance stating that it is not possible to predict phenotype from genotype; therefore predicting the pandemic risk of newly emergent strains is

not achievable given the current state of knowledge. Also, in their view, controlling outbreaks doesn't require GOF research.

Opponents of GOF research tend to favor alternative types of research that, in their view, can provide the same public health benefits without the large risks. It was suggested that the approach should be on reducing the risk by reducing the hazard, as opposed to focusing on mitigation of the risk. For example, if a universal influenza vaccine was developed, the need for many GOF experiments would be eliminated. Critics want to see funds currently used for GOF work provided to other types of research, which would be a better use of scarce resources in their view. Overall, they view preventing major public health problems as paramount, and see a need to define a critical set of experiments that should not be done, or only be done with additional strong oversight. Opponents are also concerned about proliferation and other factors that may lead to misuse and biosecurity threats. Finally, opponents have pointed out a moral issue if risks and benefits of certain GOF studies are not fairly distributed globally.

Funding Agencies

Public and private funding agencies support GOF research that has raised concerns with the goal of improving public health and well-being. These organizations in the US and abroad are aware of the issues surrounding DURC/GOF studies and are working diligently to implement and comply with existing policies in their countries. Most funders have requirements and procedures in place as they apply policies and guidance to evaluate proposed work and to oversee funded work. Current approaches involve education and awareness campaigns, project risk evaluation, ethics reviews, development of risk mitigation plans, and post-award monitoring. Funders believe they can contribute to the GOF deliberative process as a result of their practical, on-the-ground experience with DURC and GOF. They are concerned that interpreting policy can be very challenging, since it requires considerable expertise and judgment. They would welcome workable policies with clear guidance and have noted some unintended consequences of the funding pause, which affected some GOF projects that had not raised particular concerns. Some foreign government funders view government funding as a poor control mechanisms because this does not cover privately funded research and research funded by other entities. National legislation, regulations, compliance, training, awareness-raising, and self-monitoring have been noted as important.

Biosecurity Experts and Others Concerned about National Security

The ultimate goal of national security professionals, as it pertains to life sciences research, is to protect public health from natural or man-made health threats. Those concerned with national security aim to prevent terrorists and others with malicious intent or misguided motives from using products or information from GOF research to cause harm. This may include deliberate release of pathogens into the community, targeting of researchers or research facilities, or interference with on-going research activities. GOF research represents biosecurity risks in addition to biosafety risks; these overlap but are different with regard to important legal, policy and regulatory issues. Managing biosafety risks may or may not also manage biosecurity risks; GOF policy must take both types of risk into account.

When trying to assess biosecurity threats, security professionals have noted the importance of avoiding assumptions and predictions about the motives and capabilities of those who might be planning biosecurity actions. Those in the security field gather a large variety of data, but often their information is imprecise and may require consideration of what is feasible and plausible. Because of the paucity of biosecurity events, it is very difficult to evaluate and predict the likelihood and consequences of a deliberate release or determine how to prevent and/or mitigate one, and different experts view this issue very differently. It was stated that research policy in itself is not be the appropriate solution to prevent specific biological threats but specific research policies could help raise awareness of security issues among researchers, which would be important.

Security and intelligence professionals have described the challenges associated with using classification as a potential risk mitigation strategy. Classification would effectively restrict access to sensitive research information and research products and would limit the number of laboratories able to perform the studies. This could be described as both a strength and a limitation, depending on one's perspective. Life sciences research that requires classification is typically classified at the outset; the retroactive classification of research that had been conducted in an open, academic setting is exceedingly difficult.

Scientific and Medical Journals

Scientific and medical journals have been at the forefront of the GOF issue. While a number of journals and families of journals have procedures in place for identifying DURC, including GOF and other biosecurity concerns in submitted manuscripts, many journal editors are not entirely comfortable with their role. Their mission is to transmit scientific information, not control it, and they may not have the security expertise or the access to such expertise to make the necessary judgments and decisions about risks associated with communicating certain research findings. Rejection and redaction are the major tools journals have to control dissemination of dual use information, and neither may actually address the concerns; they are also impractical to implement effectively. One suggestion voiced was to require that a description of the steps that were taken during conduct of the research to ensure safety be included in all manuscripts. Some journal editors and staff expressed a desire to get help in evaluating risks and mitigation strategies from an independent national group such as the NSABB and to involve them earlier in the overall process. Most think the publication stage is not the best point to exercise control or prevent misuse of data from GOF studies but realize they are the final gatekeepers. Earlier identification of DURC/GOF along with risk mitigation earlier in the research life cycle would reduce the burden on them. Also, new technology and novel publication venues make controlling information increasingly difficult, and, as noted above, not all journals are able to or choose to impose a rigorous review of manuscripts.

Countermeasure Developers

Companies and others that are attempting to develop vaccines and drugs against pathogens were represented in several discussions. Medical countermeasure (MCM) developers expressed quite divergent views and opinions. Those favoring GOF research argued that such work is absolutely

necessary for antiviral drug development because GOF experiments to select for drug resistant mutants as well as to develop animal models are part of the critical path to marketing approval. In their view, GOF studies also have had a major influence on developing influenza vaccines, both seasonal and pandemic, and are likely to result in improved ways to make even better vaccines in the future. GOF experiments are required for selection of strains with better growth properties, with key mutations that alter important phenotypes needed in the vaccine strain, and with incorporating characteristics of strains that are likely to emerge into proven backbones. It was noted that GOF studies that enhance virulence can help inform vaccine designers about which mutations to avoid incorporating into vaccine strains. This group is concerned that their efforts to improve public health may be limited or impeded by new policies and urge careful consideration of their needs as decisions are made.

Conversely, other MCM developers expressed the view that vaccine production now is little dependent on GOF research and that any possible benefits will be far into the future, although some feel long-term potential is there. Those who criticize GOF studies on these grounds have argued that vaccines are developed in response to strains that emerge as threats, rather than preemptively based on strains that might be predicted as threats. Rather than supporting GOF studies to enhance vaccine production and drug development, it has been suggested that the other constraints that impede MCM development be addressed, such as streamlining FDA approval procedures and improving manufacturing processes, which would have a much greater impact. These critics suggest limiting current GOF-related efforts and focusing attention and resources in other directions. Overall, they believe that impact of GOF research on vaccine and drug development has been overstated, and that the benefits articulated are more theoretical than practical.

The General Public and Organizations Representing their Views.

A number of stakeholders stressed the importance of having meaningful public engagement with input and participation as part of the deliberative process. It is important that communities that might be affected by accidents or the misuse of research have a say in the research that is being conducted, however, but this may not generally be the case in their view. Real transparency, with the public good as the foremost consideration, must be part of a truly independent decision-making process. They note that it is important to maintain public trust in the scientific enterprise by involving non-scientists at stages when their views can still have an impact on policy-making. Public opinion of science is harmed when decisions that influence public health and safety are made without such input or the input has no real impact. Conversely, effective community engagement can convert sceptics to supporters. More than one participant raised the concern that if risks and benefits are not equitably distributed, it is a serious ethical issue[75].

Other issues that were mentioned include: how harms will be compensated if a laboratory incident were to affect the surrounding community; the need for enough resources to conduct research safely; and the opportunity to learn from other industries such as the nuclear industry.

[75] The ethical issues are discussed in more depth elsewhere, notably, Dr. Michael Selgelid's ethical analysis and the section of this report on Ethical Values and Decision-Making Frameworks.

Research Institutions

Representatives of universities and other research institutions generally noted that there is already significant oversight of DURC and GOF at both the Federal and institutional levels. Biosafety professionals noted that potentially high risk projects would receive thorough scientific review and risk assessment, resulting in the development of risk mitigation plans, and on-going monitoring as a result of policies and requirements that are already in place. They cited concerns over any increase in compliance that would impose burdens on their already limited resources or impede researchers from doing valuable work. They have difficulty, at times, deciding what is DURC when reviewing specific projects and would welcome more specificity and guidance. Many emphasized the need for policies that are unambiguous and straightforward to implement.

Public Health Officials

Public health officials have expressed diverse opinions. Some believe that GOF research has and can continue to improve surveillance efforts, as well as vaccine and therapeutic development. Others expressed concerns that an accident involving a laboratory pathogen for which there are no countermeasures would be very concerning and difficult to respond to. At the local level it is important to have public health involvement in the decision-making process because they will be incident responders. Strong connections with state and local laboratories should be established for sharing information and might include involving them in the review process. It was also noted that GOF and related policies may impact sample sharing and impede international relations relating to public health efforts.

International Perspectives

A number of participants noted that there is much interest in the GOF/DURC issue internationally, and the international community is looking to see what the USG will do as a result of the deliberative process. It was noted that U.S. policy often influences policies globally and the international ramifications should be considered. Recent biosafety incidents in U.S. Federal labs have raised concerns among many in other countries about the ability of the U.S. to adequately manage risks. A number of countries have well-developed systems of policy and regulation that would address many or some GOF and DURC issues, though international policy approaches are generally somewhat different from those in the U.S. International experiences, activities, and perspectives were cited as important to consider in the deliberative process. A collaborative approach and active attempts to engage the international community was viewed as the most effective way to benefit all. Many favored launching an international dialogue soon, with development of broad concepts and points of agreement that could be shared by all, while still respecting national differences. In addition, it was suggested that academies of science and multi-national organizations such as the World Health Organization can play an important role in such interactions at the right time. Those with a particular interest in the international aspects of GOF research also cited ethical issues associated with the unequal distribution of risks and benefits

across rich and poor countries. It was noted that the European Commission uses a comprehensive ethics process for screening and monitoring DURC/GOF in research projects.[76]

Those with an Interest in the Deliberative Process Itself

A broad group of individuals offered comments on the deliberative process itself. This included: federal government personnel, ethicists, decision-making experts, policy experts, other scientists, and includes people who are also members of the previously-mentioned groups. Those concerned with the deliberative process generally called for a well-planned and executed, thorough, scientifically rigorous, and impartial RBA that is technically sound and socially acceptable. They favored a democratic deliberative process and a policy that incorporates decisions made by neutral parties. Policy should be created using risk-based and value-based approaches to achieve desired outcomes. They want the final policy resulting from the deliberative process to be capable of reasonably identifying and mitigating risks related to GOF while protecting scientific autonomy, research progress, discovery and innovation, public health, national security, and other critical interests.

Many see an adaptive process as desirable, and recommend collecting appropriate data about laboratory accidents and mitigation effectiveness. It was noted that risks and benefits will change as science advances. The funding decision-making process should be accountable and limit inherent conflicts of interest; the individuals or entities that make decisions is critical. Most favor using existing policies as the basis of policy for GOF, while acknowledging that current frameworks are not entirely adequate. The question of how to incorporate non-USG funded research into an acceptable framework was raised several times. Deciding how to decide is a key point.

Both proponents and critics of GOF studies criticized the term "gain-of-function" as being too broad and not descriptive enough. There was much discussion about the appropriate definition of GOF research of concern; many strong, often conflicting, views were expressed. Unfortunately, while it is important to have a working definition and criteria for what is GOF of concern as opposed to GOF, a binary distinction needed for deciding what requires extra scrutiny, GOF experiments are actually a continuum of increasing risk.

The funding pause was criticized for being too broad, and some described it as disruptive to scientific process. Finally, some feel that a definitive quantitative risk assessment is not possible because of the very large uncertainties and lack of critical information associated with doing such studies, and they question the value of any studies that are done.

Appendix E. Consultations, Comments, and Sources Considered During NSABB Deliberations

Table 1A. Invited speakers, presenters, and panelists. This table lists invited individuals who presented at NSABB, NSABB working group, and the National Academies meetings. Members of the NSABB or an NSABB working group are listed if they presented as a subject matter expert on a specific topic.

Speaker/Commenter	Affiliation/Location	Venue
Regine Aalders, M.Sc.	Embassy of the Netherlands, Washington, D.C.	NSABB Full Board Meeting (January 7-8, 2016)
Nisreen AL-Hmoud, Ph.D, M.Phil.	Royal Scientific Society of Jordan	National Academies Workshop (March 10-11, 2016)
Ronald Atlas, Ph.D.	University of Louisville	National Academies Workshop (December 15, 2014)
Ralph Baric, Ph.D.	University of North Carolina at Chapel Hill	National Academies Workshop (December 15, 2014)
Kavita Berger, Ph.D.	Gryphon Scientific	NSABB Full Board Meeting (September 28, 2015), In-person WG Meeting (November 9, 2015)
Thomas Briese, Ph.D.	Columbia University	National Academies Workshop (December 15, 2014)
Michael Callahan, M.D., D.T.M.&H., M.S.P.H.	Massachusetts General Hospital; Harvard Medical School	National Academies Workshop (March 10-11, 2016)
Arturo Casadevall, M.D., Ph.D.	Johns Hopkins Bloomberg School of Public Health; mBio	NSABB Full Board Meeting (October 22, 2014), In-person WG Meeting (July 23, 2015)
Rocco Casagrande, Ph.D.	Gryphon Scientific	NSABB Full Board Meetings (September 28, 2015 and January 7-8, 2016), In-person WG Meeting (November 9, 2015), National Academies Workshop (March 10-11, 2016)
R. Alta Charo, J.D.	University of Wisconsin–Madison	National Academies Workshop (December 15, 2014), NSABB Full Board Meeting (January 7-8, 2016)
Susan Coller-Monarez, Ph.D.	U.S. Department of Homeland Security	In-person WG Meeting (July 23, 2015)
Louis (Tony) Cox, Ph.D., S.M.	Cox Associates	National Academies Workshop (March 10-11, 2016)
Mark Denison, M.D.	Vanderbilt University	National Academies Workshop (December 15, 2014), NSABB Full Board Meeting (January 7-8, 2016)
Dennis Dixon, Ph.D.	U.S. National Institutes of Health	NSABB Full Board Meeting (November 25, 2014)
Marianne Donker, Ph.D.	Ministry of Health, Welfare and Sport, Netherlands	In-person WG Meeting (July 23, 2015)
Philip Dormitzer, M.D., Ph.D.	Novartis Vaccines	National Academies Workshop (December 15, 2014)
Ruxandra Draghia-Akli, M.D., Ph.D.	European Commission	In-person WG Meeting (July 23, 2015), National Academies Workshop (March 10-11, 2016)
Rebecca Dresser, J.D.	Washington University in St. Louis	NSABB Full Board Meeting (September 28, 2015)
Paul Duprex, Ph.D.	Boston University, NEIDL Institute	NSABB Full Board Meeting (October 22, 2015)
Gerald Epstein, Ph.D.	White House Office of Science and Technology Policy	In-person WG Meeting (July 23, 2015)

Stephen Eubank, Ph.D.	Virginia Polytechnic Institute and State University	NSABB Full Board Meetings (October 22, 2014 and January 7-8, 2016)
Scott Ferson, Ph.D.	Applied Biomathematics	NSABB Full Board Meeting (October 22, 2014)
David Fidler, J.D., M.Phil.	Indiana University, Bloomington	NSABB Full Board Meeting (January 7-8, 2016)
Harvey Fineberg M.D, Ph.D.	University of California, San Francisco	National Academies Workshops (December 15, 2014 and March 10-11, 2016)
Adam Finkel, Sc.D., M.P.P.	University of Pennsylvania Law School	National Academies Workshops (March 10-11, 2016)
Baruch Fischhoff, Ph.D.	Carnegie Mellon University	NSABB Full Board Meeting (October 22, 2014), National Academies Workshop (December 15, 2014)
Robert Fisher, Ph.D.	U.S. Food and Drug Administration	National Academies Workshop (March 10-11, 2016)
Ron Fouchier, Ph.D.	Erasmus Medical Center	National Academies Workshop (December 15, 2014), NSABB Full Board Meeting (January 7-8, 2016)
David Franz, D.V.M., Ph.D.	Former Commander, United States Army Medical Research Institute for Infectious Diseases	In-person WG Meeting (July 23, 2015)
Christophe Fraser, Ph.D.	Imperial College	National Academies Workshop (December 15, 2014)
Richard Frothingham	Duke University	National Academies Workshop (March 10-11, 2016)
Keiji Fukuda, M.D., M.P.H.	World Health Organization	National Academies Workshop (March 10-11, 2016)
George F. Gao, D.V.M., D.Phil.	Chinese Academy of Sciences; Chinese Center for Disease Control and Prevention	National Academies Workshop (March 10-11, 2016)
Gigi Kwik Gronvall, Ph.D.	University of Pittsburgh Medical Center, Center for Health Security	National Academies Workshop (December 15, 2014), NSABB Full Board Meeting (January 7-8, 2016)
Charles Haas, Ph.D.	Drexel University	National Academies Workshop (December 15, 2014)
Andrew M. Hebbeler, Ph.D.	U.S. Department of State	NSABB Full Board Meeting (October 22, 2014), National Academies Workshop (December 15, 2014)
Ruthanne Huising, Ph.D., M.Sc.	McGill University	National Academies Workshop (March 10-11, 2016)
Gavin Huntley-Fenner, Ph.D.	Huntley-Fenner Advisors	National Academies Workshops (December 15, 2014 and March 10-11, 2016)
Jo Husbands, Ph.D.	Board on Life Sciences of the U.S. National Academies of Sciences, Engineering and Medicine	In-person WG Meeting (July 23, 2015), NSABB Full Board Meeting (January 7-8, 2016)
Michael Imperiale, Ph.D.	University of Michigan	National Academies Workshop (December 15, 2014), NSABB Full Board Meeting (January 7-8, 2016)
Thomas Inglesby, M.D.	University of Pittsburgh Medical Center, Center for Health Security	NSABB Full Board Meeting (October 22, 2014 and January 7-8, 2016)
Barbara Jasny, Ph.D.	Science	In-person WG Meeting (July 23, 2015), NSABB Full Board Meeting (January 7-8, 2016)
Daniel Jernigan, M.D., M.P.H.	U.S. Centers for Disease Control and Prevention	NSABB Full Board Meeting (January 7-8, 2016)
Barbara Johnson, Ph.D., R.B.P.	Biosafety Biosecurity International	National Academies Workshop (December 15, 2014)
John Kadvany, Ph.D.	Independent consultant on decision science	Full Board Meeting (January 7-8, 2016)
Joseph Kanabrocki, Ph.D., C.B.S.P.	University of Chicago	In-person WG Meeting (January 22, 2015), In-person WG Meeting (July 23, 2015)

Isidoros Karatzas, Ph.D.	European Commission	WG Meeting (February 16, 2016)
Yoshihiro Kawaoka, D.V.M., Ph.D.	University of Wisconsin, Madison	NSABB Full Board Meetings (October 22, 2014 and January 7-8, 2016), National Academies Workshop (December 15, 2014)
George Kemble, Ph.D.	3-V Biosciences	National Academies Workshop (December 15, 2014)
Lawrence Kerr, Ph.D.	U.S. Department of Health and Human Services	WG Meeting (November 5, 2015), National Academies Workshop (March 10-11, 2016)
Gregory Koblentz, Ph.D., M.P.P.	George Mason University	National Academies Workshop (December 15, 2014)
Todd Kuiken, Ph.D.	The Woodrow Wilson Center	In-person Meeting (July 23, 2015)

Appendix F. NSABB Framework for Guiding the Risk and Benefit Assessments

The National Science Advisory Board for Biosecurity developed the recommendations contained in the following section as part of its charge stemming from the *U.S. Government Gain-of-Function Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS viruses*. As part of its charge, the NSABB was to provide advice on the design, development, and conduct of risk and benefit assessments for gain-of-function studies. The *Framework for Guiding the Conduct of Risk and Benefit Assessments of Gain-of-Function Research* which follows fulfills this portion of the NSABB's charge and was developed with the aim of helping to generate risk and benefit assessments that would provide information that would allow the NSABB to make sound, evidence-based recommendations.

FRAMEWORK FOR CONDUCTING RISK AND BENEFIT ASSESSMENTS OF GAIN-OF-FUNCTION RESEARCH

RECOMMENDATIONS OF THE NATIONAL SCIENCE ADVISORY BOARD FOR BIOSECURITY

National Science Advisory Board for Biosecurity
MAY 2015

TABLE OF CONTENTS

PREAMBLE

The National Science Advisory Board for Biosecurity developed the recommendations contained in this document as part of its charge stemming from the *U.S. Government Gain-of-Function Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS viruses*, issued on October 17, 2014. As part of its charge, the NSABB is to 1) provide advice on the design, development, and conduct of risk and benefit assessments for gain-of-function studies, and 2) provide formal recommendations on the conceptual approach to the evaluation of proposed gain-of-function studies. This document was unanimously approved by the committee on May 5, 2015 and fulfills the first portion of the NSABB's charge. The recommendations in this document will guide the National Institutes of Health as it commissions a formal assessment of the potential risks and benefits associated with gain-of-function research involving pathogens with pandemic potential. The results of the risk and benefit assessments will inform the NSABB as it develops its recommendations to the United States Government about how to evaluate such studies.

BACKGROUND AND INTRODUCTION

Most genetic manipulations of microorganisms do not raise significant safety or security concerns; these studies are routinely conducted for valid scientific purposes using non-pathogenic organisms or biologic systems and are subject to appropriate Federal and institutional oversight. However, safety and security concerns may arise when certain types of manipulations, which introduce stable genetic mutations, are employed to better understand some pathogens or toxins, sometimes enhancing the ability of those agents to harm their hosts.

Recently, the phrase "gain-of-function (GOF) research" has come to describe certain studies that increase the ability of a pathogen to cause disease. This phrase achieved prominence after two groups published findings demonstrating that highly pathogenic avian influenza H5N1 viruses with a small number of engineered mutations became transmissible between mammals by respiratory droplets.[77,78] Such studies were undertaken to help define the fundamental nature of human-pathogen interactions, with the goal of enabling assessment of the pandemic potential of emerging infectious agents, informing public health and preparedness efforts, and furthering medical countermeasure development. However, such GOF studies may entail biosafety and biosecurity risks, and significant concerns have been raised about whether these studies generate information that could be misused to cause harm or whether the modified viruses could pose a pandemic threat if they were to be accidentally or intentionally released.

In 2012, a voluntary suspension of certain GOF studies involving highly pathogenic avian influenza H5N1 viruses was undertaken by the influenza research community.[79] During that time, policymakers considered whether certain GOF studies should be conducted using Federal funds, and if so, how those studies could be safely conducted. The Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) issued new biosafety guidelines for working with highly pathogenic avian influenza strains.[80,81] The U.S. Department of Health and Human Services (HHS) developed a framework for guiding its funding decisions about projects that may generate highly pathogenic H5N1 viruses that are transmissible between mammals by respiratory droplets.[82] This funding framework was later expanded to include H7N9 influenza viruses as well.[83] Under this framework, HHS considers newly submitted research project proposals involving certain GOF studies for their scientific and public health merits as well as associated biosafety, biosecurity, and dual use risks. HHS also identifies appropriate risk mitigation measures that are required. Studies that are deemed acceptable for funding may then proceed in accordance with any agreed-upon risk mitigation measures.

Given the biosafety incidents in U.S. Federal laboratories during the summer of 2014 and renewed concerns regarding laboratory safety and biosecurity, the U.S. government (USG) determined that the risks and benefits of GOF research must be re-evaluated.[84] A robust and broad deliberative process that will result in the adoption of a new Federal GOF research policy (which will apply to research funded by U.S. agencies whether conducted in the U.S. or abroad) has been undertaken. While this process takes place, the USG has instituted a pause in the provision of new USG funding for certain GOF research involving influenza, Middle East Respiratory Syndrome coronavirus (MERS) or Severe Acute Respiratory Syndrome coronavirus (SARS) viruses—pathogens determined to have pandemic potential. Restrictions on new funding apply as follows:

> *New USG funding will not be released for gain-of-function research projects that may be reasonably anticipated to confer attributes to influenza, MERS, or SARS viruses such that the virus would have enhanced pathogenicity and/or transmissibility in mammals via the respiratory route. This restriction would not apply to characterization or testing of naturally occurring influenza, MERS, and SARS viruses, unless the tests are reasonably anticipated to increase transmissibility and/or pathogenicity.*

In parallel, the USG has encouraged the research community (both those who receive USG funding and those who do not) to join in adopting a voluntary pause on any on-going research that involves the types of studies that are subject to the funding restriction above.

The deliberative process involves both the National Science Advisory Board for Biosecurity (NSABB) and the National Academies, and involves explicit evaluation of the possible risks and potential benefits of GOF research with potential pandemic pathogens. The NSABB serves as the official Federal advisory body for providing advice on oversight of this area of dual use research. The NSABB is providing the USG with specific recommendations regarding a conceptual approach to the evaluation of proposed GOF studies. The National Research Council and the Institute of Medicine of the National Academies are convening forums to engage the life sciences community as well as to solicit feedback from scientists and the public on optimal approaches to ensure effective Federal oversight of GOF research. These forums involve discussion of principles important for the design of risk and benefit assessments of GOF research and of NSABB draft recommendations.

The final NSABB recommendations and the discussions at the National Academies forums will be taken into consideration by the USG during the development and adoption of a new USG policy governing the funding and conduct of GOF research.

Thorough and scientifically rigorous risk and benefit assessments of GOF research involving pathogens with pandemic potential are needed to inform the deliberative process, and to provide the NSABB and the USG with objective and comprehensive information about the risks and benefits associated with certain types of GOF research. The USG has determined that an independent contractor will conduct the risk and benefit assessments (RA and BA). The contractor will provide personnel and expertise for conducting the RA and BA on certain GOF research involving pathogens with pandemic potential. The RA and BA are to be comprehensive, sound, and credible and must be able to withstand rigorous scrutiny by a variety of stakeholders. The contractor's analyses are to be guided by the overall guiding

[84] *U.S. Government Gain-of-Function Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS viruses*, October 17, 2014.

principles described herein. In planning and conducting the RA and BA, the contractor will take into account issues raised by recent biosafety incidents in USG laboratories.

While the funding pause and the RA and BA are limited to specific pathogens,[85] products of the RA and BA are intended to inform broader NSABB deliberations, which will involve recommendations on a conceptual approach to the evaluation of proposed GOF studies that may extend to other high-consequence pathogens. NSABB recommendations will inform the USG as it develops and adopts policies about whether certain types of GOF studies on high-consequence pathogens with pandemic potential should be supported and, if so, how such funding proposals should be evaluated.

A private contractor will conduct the RA and BA; however, the process is intended to be a cooperative effort involving participation by NIH and the NSABB, and informed by discussions held at the National Academies forums. The NIH Office of Science Policy is managing the overall deliberative process, providing the interface and facilitating the communications between the contractor and other entities, and overseeing the work by the contractor. The studies and resulting reports must comply fully with USG requirements, both procedurally and analytically, using existing guidance from Federal agencies and peer-reviewed sources and well-established methods. Concerns of other stakeholders, in addition to the USG, must be considered.

THE CHARGE TO THE NSABB

The NSABB has been charged with providing advice on the design, development, and conduct of risk and benefit assessments, and with providing recommendations to the USG on a conceptual approach to the evaluation of proposed GOF studies. In developing its recommendations, the NSABB will consider: the results of the RA and BA; the spectrum of potential risks and benefits associated with GOF studies; alternative methods that may be employed to yield similar scientific insights or benefits, while reducing potential risks; public discussions hosted by the National Academies; and any additional consultations with relevant subject matter experts, as needed, to ensure that all appropriate expertise is brought to bear on the issues. In advising on the design and conduct of the RA and BA, the NSABB will recommend assumptions to be included in the risk assessment; evaluate the scope and methodologies to be used in the risk assessment; consider the adequacy of the scenarios in the risk assessment and propose additional scenarios to address other concerns or factors, as appropriate; advise on the assessment of the benefits, including types of benefits that should be examined and methods for examining them; and provide advice at key milestones in the conduct of the RA and BA.

To satisfy this charge, the NSABB will convene, deliberate, and provide two deliverables to the USG:

- **Deliverable 1.** Advice on the design, development, and conduct of risk and benefit assessments.
- **Deliverable 2.** Formal recommendations on the conceptual approach to the evaluation of proposed GOF studies.

The framework outlined herein, and subsequent input provided by the NSABB at key milestones throughout the conduct of the RA and BA, are intended to satisfy Deliverable 1.

---

[85] *U.S. Government Gain-of-Function Deliberative Process and Research Funding Pause on Selected Gain-of-Function Research Involving Influenza, MERS, and SARS viruses*, October 17, 2014.

THE NSABB'S PROCESS

In order to accomplish its charge regarding Deliverable 1, the NSABB established a Working Group (WG), composed of 13 NSABB members with a broad range of expertise including microbiology, biodefense, ethics, biosecurity, national security, biosafety, public health, and other relevant areas. The WG also included non-voting *ex officio* members from Federal agencies who contributed expertise in virology, national security, ethics, foreign policy, and other areas. The group convened during the period of December 2014 through April 2015 by telephone conference calls and held a one-day in-person meeting to discuss the design and conduct of the RA and BA and to begin to identify the information necessary to inform the Board's final recommendations to be issued in Deliverable 2. The discussions ranged broadly and included general concepts of overall importance as well as specific details that the contractor should consider and include as the RA and BA proceed. The WG's findings were consolidated into a series of recommendations that were discussed and developed further, and ultimately approved by the full Board on May 5, 2015. The recommendations in this Framework are intended to guide the NIH as it works with the contractor performing the RA and BA such that the assessments will be conducted in a way that will provide information that allows the NSABB to make sound, evidence-based recommendations. The NSABB acknowledged the strengths and limitations associated with such assessments, which primarily involve scientific and technical input, and has noted that other information, such as consideration of ethical, legal, and other viewpoints, should inform its final recommendations (Deliverable 2).

In guiding the design of the RA and BA, the NSABB focused on issues specific to GOF studies but noted that some other directly relevant studies are important for comparison and should be included in the assessments. Although the RA and BA focus on specific experiments and scenarios, the scope is intended to be sufficient to allow evaluation of the risks and benefits of not just single experiments, but also whole research programs to inform decisions pertaining to the entire USG research portfolio related to GOF studies with high consequence pathogens with pandemic potential.

Finally, an issue of central importance to the entire deliberative process is public trust in the scientific enterprise. A possible negative outcome associated with the GOF issue is the loss of public trust if a laboratory accident involving modified strains were to occur or if GOF research were intentionally misused to cause harm. Loss of public trust is a serious concern and its impact could be felt widely across the scientific community. The deliberative process should be conducted with an eye toward maintaining public trust in the scientific enterprise and oversight of scientific research. To help ensure public trust, and to ensure the NSABB's deliberations are informed by broad input and diverse perspectives, the NSABB seeks to maximize stakeholder input and public engagement during the deliberative process. Of note, the deliberative process includes public forums hosted by the National Academies that are intended to gather input and foster broad discussions by the scientific and other stakeholder communities. The first forum was held in December 2014;[86] a second will be held later in the process. Additionally, NSABB meetings are open to the public and the Board encourages attendees to provide comments, either verbally or in writing. The NSABB encourages comments and input at any time, which can be submitted by emailing NSABB@od.nih.gov.

RECOMMENDATIONS REGARDING THE DESIGN AND CONDUCT OF THE RA AND BA

Guiding Principles

Listed below (not necessarily in order of importance) are guiding principles that should underpin the risk and benefit assessments. These principles should inform and guide the contractor's efforts in performing the risk and benefit assessments.

1. There are potential risks and benefits associated with certain GOF life sciences research that should be formally and rigorously identified and analyzed. The possible risks and benefits of not doing this work also need to be thoroughly examined.

2. Alternative experimental approaches to GOF experiments that may provide the same or similar outcomes or additional/different benefits, without the same risks, should be identified and their relative risks, benefits, and limitations thoroughly and impartially analyzed. There may be different risks and benefits associated with these alternatives.

3. The RA and BA processes should start with a clear articulation of their purposes. The issues must be framed appropriately, with specific, relevant questions to be answered. The RA and BA should be conceptualized so as to provide information that is useful and informative for guiding NSABB recommendations about whether or not and how to pursue the types of scientific studies that are the subject of the assessments.

4. The scope of the RA and BA must be sufficiently comprehensive and delineated, with all aspects of the problem being clearly defined and considered at the outset. While the scope must be sufficiently detailed, it also must be appropriately narrowed to the particular subset of studies whose risks may be especially significant.

5. The concepts of clarity, transparency, consistency, and reasonableness must underpin the RA and BA. The processes must be well-documented and the final results and their interpretations should be clearly described and presented.

6. The assessments must be objective, scientifically rigorous, comprehensive, credible, and reasonable. Analyses of potential risks and benefits should be based on existing guidance, use real data to the extent possible, and employ established, tested, and peer-accepted methods. The RA and BA should include both qualitative and quantitative analyses to the extent feasible.

7. Analyses should examine the impact of risk mitigation strategies and practices, the effect of public health interventions, and whether countermeasures are effective against novel strains, as well as how these strategies are actually employed, which may involve human error, crisis conditions, or other factors that decrease their effectiveness.

8. The data used are critical to conducting the risk and benefit assessments. Sources of data, quality of data, assumptions made in analyses, limitations of data, and areas where more data are needed all require explicit documentation. However, insufficient or lack of quality data should not be grounds for not addressing issues pertinent to the goals of the assessments.

Particular consideration must be given to issues of uncertainty[87] and sensitivity[88] in presenting results. Ranges and bounds should be used to reflect the level of confidence in the results.

9. The RA should address what could go wrong as a result of conducting GOF research, and the probability and consequences of such events. The BA should address what beneficial outcomes might result from such research, how probable they are, the magnitude of their effects, and a realistic timeframe for realizing the benefits. Both risks and benefits may depend on other factors and have different timeframes. Any assumptions regarding factors that must be present for the risks or benefits to be realized should be explicitly identified.

10. The focus of the assessments should be on research studies conducted within the U.S. or supported by U.S. funding and conducted outside of the U.S., but should take into account the fact that laboratories throughout the world that are not funded by the U.S. government may also be conducting similar studies.

11. These principles largely apply to both the RA and BA; however, the benefits are not just reduction of the risks included in the risk assessment. It may not always be feasible to express risks and benefits in the same terms, but an effort should be made to do so when possible.

12. The RA must encompass a range of scenarios including "maximum reasonable foreseeable events" (i.e., worst case) as well as those with a range of probabilities. Low probability but high consequence events deserve particular attention. Both intentional (malevolent) and accidental events should be included in the analyses.

Pathogens and Pathogen Characteristics

Listed below are pathogens that are recommended for inclusion in the RA and BA to provide information about the risks and benefits associated with GOF research involving these specific agents; however, the NSABB's ultimate policy recommendations need not be limited to these specific pathogens. The risks and benefits analyzed in the assessments are intended to be representative of those associated with similar agents and experiments that may arise in the future. Most pandemics are associated with respiratory transmission, so agents in this category are of overarching concern. The NSABB considered adding a variety of agents, viral and bacterial, as well as agents having different transmission routes that might gain the property of respiratory transmission. The NSABB also discussed the pathogen characteristics that are most concerning.

[87] Uncertainty is the lack or incompleteness of information. Quantitative uncertainty analysis attempts to analyze and describe the degree to which a calculated value may differ from the true value; it sometimes uses probability distributions. Uncertainty depends on the quality, quantity, and relevance of data and on the reliability and relevance of models and assumptions used to fill data gaps. From *Science and Decisions: Advancing Risk Assessment*. National Research Council of the National Academies, The National Academies Press; Washington DC. 2009.

[88] Sensitivity is the degree to which the outputs of a quantitative assessment are affected by changes in selected input parameters or assumptions. From *Science and Decisions: Advancing Risk Assessment*. National Research Council of the National Academies, The National Academies Press; Washington DC. 2009.

Pathogens recommended for inclusion in the RA and BA:

1. **Influenza viruses.** Because of the significant differences among influenza strains, the NSABB recommends that three distinct strains be analyzed. These are:

    a. Seasonal influenza (e.g., currently circulating or historical H1N1, H3N2, and influenza B strains for which a significant portion of the general population has pre-existing immunity)
    b. Highly pathogenic avian influenza virus H5N1
    c. Low pathogenic avian influenza virus H7N9

2. **SARS-CoV**

3. **MERS-CoV**

Pathogen characteristics recommended for consideration in the RA and BA:

The RA and BA should include analysis of the risks and benefits associated with GOF experiments that are anticipated to increase the pandemic potential of pathogens. Toward this end, the following characteristics, which may be conferred to pathogens during the conduct of GOF studies, should be considered:

1. Enhanced pathogen production as a result of changes in the replication cycle or growth.

2. Enhanced morbidity and mortality in appropriate animal models.

3. Enhanced transmission in mammals (e.g., increased host or tissue range, altered route of transmission, infectivity above a certain threshold determined in an appropriate animal model).

4. Evasion of existing natural or induced immunity.

5. Resistance to drugs or evasion of other medical countermeasures such as vaccines, therapeutics, diagnostics.

Risk Categories

In order for the contractor to plan and conduct the risk assessment so that it will ultimately meet the needs of the NSABB, the scope of possible risks must be defined at the outset. The risk assessment should particularly examine any risks that are unique to GOF studies and examine the relative risks of GOF research compared to alternative approaches. It is important that all reasonable categories of risks be examined. Listed below are the categories of risks that the NSABB recommends be considered in the RA. There is some overlap between the categories, and of note, potential national biosecurity risks that should be considered are associated with most of the categories. For each of the risk categories, both intentional and accidental events that lead to risk should be considered, as appropriate. In addition, the analysis should consider the risks associated with certain GOF studies in the context of currently existing risks associated with the broader, national biomedical research portfolio and from the perspective of past experience. The RA should also consider the additive risks associated with conducting relevant GOF

studies at multiple locations. Where there are case studies or known examples of events that document various risks, these should be compiled and selected examples incorporated into the RA report.

1. **Biosafety:** Biosafety risks are those generally associated with laboratory accidents. Assessing these risks should include the magnitude of exposures, initial infections, transmission leading to secondary infections, and outbreaks in humans or animals. The issue of novel pathogenic strains for which we may be unprepared needs particular attention. The association of laboratory personnel with intermediary hosts should also be considered. The RA should evaluate the effect that public health interventions and occupational health and staff monitoring programs have on the risks posed by novel pathogens resulting from GOF studies, as compared to existing pathogens. The assessment should consider how the capabilities and containment features of the lab doing the work influence risk. The risks to lab workers and to the general public should be analyzed separately.

2. **Physical and personnel security (biosecurity):** Biosecurity risks are those associated with crime and terrorism involving pathogens resulting from GOF studies and would take into account the physical security of pathogens, risks associated with shipping and transporting pathogens, and the risk of illegitimate acts by "insiders," or laboratory employees. Biosecurity risks include physical breach, theft, loss or intentional release by lab personnel, malevolent acts, and terrorism. The RA should include consideration of the types of actors who would seek to misuse life sciences research information and materials as well as their capabilities to do so. The analysis should also consider specifically how the studies in question could be misused, whether terrorists might target labs to gain access to materials or scientific expertise, and include estimates of how great the threats may be.

3. **Proliferation:** The RA should consider how pursuing certain GOF studies may lead to expanded amounts of that research and, as a result, increased risk (biosafety, biosecurity, and others). Proliferation might occur if certain studies become standard or typical, or, conversely, if unpublished studies (due to safety or security concerns) are repeated, unwittingly by others. This analysis should take into account that biosafety standards vary in different countries and settings.

4. **Information risk:** Information risks are those associated with how the information generated by GOF studies, if made publically available, could enable others throughout the world to replicate such studies or generate pathogens for malevolent actions or threats to national security. Intellectual property threats may also be considered here.

5. **Agricultural:** This involves the risks to agriculturally-relevant animals such as pigs or chickens if a laboratory-modified pathogen produced during GOF studies was to be intentionally or accidentally released into populations of these animals. This also includes risks resulting from interaction between humans and other reservoir hosts.

6. **Economic risks:** Economic risks include monetary costs associated with releases of pathogens resulting from GOF studies, including loss of productivity, agricultural damage, liability, and the issue of accountability. Opportunity costs might also be considered.

7. **Loss of public confidence:** It is important to consider the possible loss of public trust in the scientific enterprise that might result if a laboratory accident involving modified pathogens were

to occur or if products or information from GOF research were intentionally misused to cause harm. Loss of public trust is a serious concern and its impact could be felt widely across the scientific community.

Benefit Categories

In order for the contractor to plan and conduct the BA so that it will ultimately meet the needs of the NSABB, the scope of potential benefits that may result from GOF research must be defined at the outset. The BA should particularly examine any unique benefits that could be realized as a result of GOF studies and examine the relative benefits of GOF research compared to alternative approaches. It is important that all reasonable categories of benefits be examined. Listed below are several categories of benefits that the NSABB recommends for inclusion in the BA. It should be noted that national security dimensions to the benefits associated with several categories should be considered. The NSABB notes that some benefits may only accrue if other associated events also take place. The NSABB also acknowledges the difficulty of analyzing some benefits, particularly those with long-term timeframes.

1. **Scientific knowledge**: These benefits include analysis of the types of scientific information that could be generated from GOF research, and an assessment of the value of such information for understanding the agents/diseases being studied (or other agents/diseases). The assessment should consider ways to quantify these benefits if possible. The BA should also analyze whether GOF research generates (or is likely to generate) unique scientific information that expands the knowledge base in ways that other research approaches cannot.

2. **Biosurveillance:** These benefits would include those relevant to the processes of gathering, integrating, analyzing, interpreting, and communicating essential information that might relate to disease activity and threats to human, animal, or plant health.[89] Specifically, the potential benefits of relevant GOF studies should be examined for benefits to:

   a. **Public Health Surveillance[90]:** How GOF research may contribute to efforts to improve public health by aiding detection and monitoring of pathogens in the real world, or help to better recognize or predict outbreaks in human populations, and inform decision-making.

   b. **Agricultural and domestic animal surveillance:** How GOF research may contribute to efforts to improve agricultural health by aiding detection and monitoring of pathogens in

[89] The National Association of County and City Health Officials, http://naccho.org/topics/emergency/biosurveillance/index.cfm, defines biosurveillance as a process of gathering, integrating, interpreting, and communicating essential information that might relate to disease activity and threats to human, animal, or plant health. For the public health professional, biosurveillance activities range from standard epidemiological practices to advanced technological systems, utilizing complex algorithms.
[90] The World Health Organization, http://www.who.int/topics/public_health_surveillance/en/, defines public health surveillance as the continuous, systematic collection, analysis and interpretation of health-related data needed for the planning, implementation, and evaluation of public health practice. Such surveillance can serve as an early warning system for impending public health emergencies; document the impact of an intervention, or track progress towards specified goals; and monitor and clarify the epidemiology of health problems, to allow priorities to be set and to inform public health policy and strategies. CDC defines public health surveillance as the ongoing, systematic collection, analysis, and interpretation of health data, essential to the planning, implementation and evaluation of public health practice, closely integrated with the dissemination of these data to those who need to know and linked to prevention and control. See http://www.cdc.gov/niosh/topics/flu/surveillance.html.

food-producing, domestic, or other animals so as to help to better recognize or predict outbreaks in such animals, and inform decision-making.

c. **Wildlife surveillance:** How GOF research may contribute to the improvement of surveillance in wildlife by aiding detection and monitoring of pathogens, or help to better recognize or predict outbreaks in such animals, and inform decision-making.

3. **Medical countermeasures:** For the following three benefits in particular, the benefit assessment should examine the relative benefits of GOF research compared to alternative approaches. The assessment should also consider whether, and if so, how, GOF research yields unique information that may not otherwise be possible.

   a. **Therapeutics**: How the research is likely to aid discovery and development of new or more effective therapeutics.

   b. **Vaccines:** How the research is likely to aid development and selection of new or more effective vaccines.

   c. **Diagnostics:** How the research is likely to aid development of new or better diagnostic methods and products.

4. **Informing policy decisions:** How information gained from GOF studies contributes, or is likely to contribute, to public health preparedness decisions such as informing countermeasure stockpiling decisions, guiding decisions about strain selection for vaccine development, or informing decisions about whether and how to mobilize resources or issue guidance in response to a newly emergent pathogen.

5. **Economic benefits:** Possible gains (monetary, employment, labor productivity, etc.) and cost savings associated with the results/outcomes of GOF studies, such as diminished health care costs due to vaccines or therapeutics, or other positive impacts on the economy.

Historical Perspectives from Analysis of Past Experiences

Naturally-occurring epidemics and pandemics can provide helpful background information that might inform the discussion about the risks associated with the infectious agents that are subjects of RA and BA. There is significant historical data on the mortality and morbidity associated with seasonal and pandemic influenza, as well as more recent data on the other pathogens recommended for inclusion the RA and BA studies. However, there are complexities and limitations to interpreting these data and trends that require further analysis. Valuable historical perspectives about past outbreaks of seasonal and pandemic influenza, SARS, and MERS viruses could be obtained by conducting quantitative analyses of global pathogen-associated morbidity and mortality. This information will supplement the RA and BA being undertaken as part of the deliberative process on GOF research, and will help inform the development of the NSABB's final recommendations (Deliverable 2).

Specifically, the NSABB recommends that an analysis be done for each pathogen, which summarizes existing data and information and, to the extent possible, includes:

1. Global morbidity and mortality data associated with seasonal influenza, pandemic influenza, SARS, and MERS, and trends in these data over time.

2. If applicable, comparison of the morbidity and mortality associated with seasonal and pandemic illness.

3. Historical information about the impact of illness on food production, particularly the swine and poultry industries.

4. Description of how the data utilized were collected, interpreted, and analyzed.

5. Qualitative review of the impact of vaccines and therapeutics on pathogen-associated morbidity and mortality.

Scenarios and Events to be Included in the RA

The RA should be based on a series of events that might occur during the course of conducting GOF research. It is anticipated that the contractor will develop a large list of possible events and scenarios that might be included. Because of time and resource constraints, only a subset will be analyzed in depth; however, it is important to define the total range of reasonably likely events so that the ones that are analyzed will be representative of the risks anticipated to be associated with GOF research more broadly. Scenarios should include analysis of the effects of risk mitigation approaches and include realistic examples where mitigation is effective and where it fails in some way. The analyses should incorporate examples that account for variability between labs and their practices.

Development and Selection of Events and Scenarios

Listed below are recommendations, derived from the Guiding Principles identified above, which should guide the contractor as specific scenarios are developed and proposed for analysis.

1. Scenarios and events should be scientifically, politically, and socially accurate and credible.

2. To the extent possible, events and scenarios should be realistic and based on actual examples, possibly including the recent laboratory accidents at Federal facilities.

3. The overall range of scenarios should encompass high and low risk events, high and low probability events, and maximum reasonably foreseeable (highly unlikely, but still credible) events.

4. The scenarios should involve events that are of concern to stakeholders, including the public, and include types that involve experimental manipulations that ultimately may be determined to be prohibited under any circumstances.

5. Scenarios involving security threats should be plausible but not necessarily based on specific, real-life examples, given that the security landscape is constantly evolving. Such scenarios should involve consideration of the prior actions or expressed intent of hostile groups, current and reasonably achievable technical capabilities of these groups, and how readily security threats could be achieved or enabled by a certain type of GOF study.

Categories of Events and Scenarios

Listed below are types of events and scenarios that the NSABB recommends for consideration in the RA. The contractor should propose more specific scenarios based on these categories.

1. Accidents due to equipment failure, human error, and system malfunction
2. Events that lead to direct infection of lab worker(s)
3. Accidental direct release into the environment, with possible exposure of the public
4. Scenarios that lead to secondary transmission of disease in the community, starting with an infected lab worker
5. Incidents that result from security failures, either building systems or personnel
6. Incidents stemming from inventory errors and those involved with laboratory transitions, such as laboratories relocating, principal investigators retiring, students graduating, etc.
7. Scenarios involving the escape of an infected animal
8. Scenarios that result in health and/or economic impacts on important animal species, particularly those important to the food supply
9. Insider threats: an internal breach of security (e.g., disgruntled lab worker, infiltration of a lab by an individual with nefarious intent)
10. External threats: an external breach of security (e.g., crime, targeting of a lab for theft of agents or materials)
11. Production of novel pathogens for malevolent acts or other illegitimate purposes based on information published about the results of GOF research
12. Natural disasters (e.g., earthquake, hurricane, tornado)
13. Accidents resulting from conduct of GOF research under sub-standard biosafety/biocontainment conditions or practices, either in the U.S. or internationally
14. Scenarios based on alternative experimental approaches to GOF research

Types of Experiments in RA

The scope of research that is of concern must be clearly defined at the outset. Not all research that involves genetic manipulations to alter a pathogen's phenotype should be examined in the RA and BA. Listed below are types of experiments recommended for consideration in the RA and BA, but the NSABB's ultimate policy recommendations need not be limited to the specific experiment types included in the assessments. The following list includes experiment types that should be incorporated into

scenarios to be modeled in the RA. Importantly, inclusion of these types of experiments is not intended to condemn or condone them. The goal is to get a broad sense of the risks and benefits associated with different experimental manipulations in the context of the pathogens identified above, recognizing that not all permutations of risks, agents, and scenarios can practically be analyzed in depth.

1. Passage in animals with the intent to alter host range and generate mammalian adapted strains or to develop an animal model of disease
2. Genetic modifications and/or selection for traits that may increase pathogenicity or transmissibility
3. Manipulations resulting in better growth or enhanced replication, for example, to make a vaccine strain
4. Selection for drug-resistant mutants
5. Antigenic escape studies, i.e., selecting for pathogens that are not neutralized by certain antibodies, such as those generated in response to a vaccine or monoclonal antibodies
6. Alternative experiments to GOF that may yield similar scientific information

Biosafety Assumptions for the RA

In order to assess the risks associated with GOF experiments it is necessary to define the biosafety level (BSL) and other related conditions under which the work may take place because differences in working conditions may significantly affect the risk of an experiment and possible adverse results. In the United States, the *Biosafety in Microbiological and Biomedical Laboratories* and the *NIH Guidelines for Research Involving Recombinant or Synthetic Nucleic Acid Molecules* (*NIH Guidelines*)[91] provide biosafety guidance regarding the conduct of risk assessments, and determination of appropriate laboratory practices and physical containment for research conducted with specific agents. These guidelines apply to certain Federally-funded research conducted in the U.S. and abroad and are frequently used by non-Federally-funded institutions and other countries as the model for biosafety guidance. The NSABB recommends that the contractor carefully examine current guidance for biocontainment, biosafety practices, training, and occupational health plans and incorporate these features into their analysis.

Different countries have varying biosafety standards, and not all individuals replicating GOF work (especially including those intending to misuse their materials or results) will necessarily abide by biosafety standards. Therefore, to examine the range of risks associated with conducting GOF studies under different biosafety conditions, the NSABB recommends that risks associated with GOF studies involving each pathogen be assessed both 1) under biosafety conditions that are recommended under current guidance for the relevant studies and 2) under a range of biosafety conditions, so that the effects of different levels of mitigation, or lack thereof, can be determined. Also, the NSABB recommends that the effects of adequate or inadequate occupational medicine/medical surveillance programs, training, standard operating procedures, and administrative controls be examined. This approach will provide information the NSABB needs to make recommendations about the conditions under which certain GOF studies might be performed to maximize safety and minimize unnecessary

[91] http://osp.od.nih.gov/office-biotechnology-activities/biosafety/nih-guidelines

burden on the research. Finally, the NSABB recommends that the contractor investigate the status of biosafety guidance and biocontainment capabilities in other parts of the world, including guidance issued by the World Health Organization, and provide a summary of the findings.

Approaches and Methods for Assessing Risks and Benefits Associated with GOF Studies

The NSABB recommends that the following approaches be explored and employed by the contractor, as appropriate and reasonable, to assess the risks and benefits associated with relevant GOF studies. The contractor should examine these and other possible methods and identify those that might best be used to assess the specific categories of risks and benefits recommended above. Efforts to identify risks and benefits that are unique to GOF research should be emphasized.

1. Literature reviews and examination of knowledge indicators (e.g., science citation index), including consideration of quality and impact of information on the field.

2. Examination of commercialization indicators (e.g., number of patents), including considerations for quality and utility.

3. Interviews and consultations with a broad range of relevant experts about risks and benefits associated with GOF studies are highly recommended. Relevant experts might include those in various scientific disciplines, public health, clinical medicine, agriculture, private sector, global health, public policy, and national security, and should include experts both within and outside the United States. Consultations should include discussion of the important scientific questions remaining specifically for the pathogens being analyzed in the RA and BA and whether and how information from GOF studies may be utilized by relevant sectors. Discussions of how GOF studies contribute to research involving other pathogens with pandemic potential may also be useful. Interviews should also incorporate discussion of the perceived risks and benefits of alternatives to GOF studies.

4. Development of illustrative case studies or descriptions of instances where a GOF study has resulted in a specific risk or benefit.

5. Quantitative approaches to modeling the risks and benefits, particularly to public health. For instance, morbidity and mortality may be modeled for various scenarios of laboratory accidents, security breaches or intentional misuse, and/or public health responses. Additionally, if a GOF study were to accelerate vaccine or therapeutic production, it may be possible to model the positive effects on public health.

6. Quantitative approaches to modeling economic benefits and risks. For instance, if a GOF study would accelerate the development of a therapeutic or vaccine, the potential positive effects on jobs or productivity, as well as reduced health care costs in the event of a pandemic, might be estimated. In addition, the costs associated with an accidental release or malevolent act should be modeled.

7. Development of “event trees” illustrating processes leading to tangible events from GOF studies, employing expert elicitation to bound key events/nodes in processes.

Appendix G. NSABB Charter

THE SECRETARY OF HEALTH AND HUMAN SERVICES
WASHINGTON, D.C. 20201

CHARTER

NATIONAL SCIENCE ADVISORY BOARD FOR BIOSECURITY

AUTHORITY

Authorized by 42 U.S.C. 217a, section 222 of the Public Health Service Act, as amended and Pub. L. 109–417, section 205 of the Pandemic and All-Hazards and Preparedness Act. The National Science Advisory Board for Biosecurity (NSABB) is governed by the provisions of the Federal Advisory Committee Act, as amended (5 U.S.C. app.), which sets forth standards for the formation and use of advisory committees.

OBJECTIVES AND SCOPE OF ACTIVITIES

The purpose of the NSABB is to provide, as requested, advice, guidance, and leadership regarding biosecurity oversight of dual use research, defined as biological research with legitimate scientific purpose that may be misused to pose a biologic threat to public health and/or national security. The NSABB will provide advice on and recommend specific strategies for the efficient and effective oversight of federally conducted or supported dual use biological research, taking into consideration both national security concerns and the needs of the research community to foster continued rapid progress in public health and agricultural research. Toward this end, the NSABB will also include providing strategies to raise awareness of dual use issues relevant to the life science and related interdisciplinary research communities.

DESCRIPTION OF DUTIES

The NSABB will be composed of subject matter experts who are not full-time employees of the Federal Government as well as ex officio members from Federal entities listed in the "Membership and Designation" section below, and will perform the following activities:

- Provide recommendations on the development of programs for outreach, education and training in dual use research issues for scientists, laboratory workers, students, and trainees in relevant disciplines.
- Advise on policies governing publication, public communication, and dissemination of dual use research methodologies and results.
- Recommend strategies for fostering international engagement on dual use biological research issues.

- Advise on the development, utilization and promotion of codes of conduct to interdisciplinary life scientists, and relevant professional groups.
- Advise on policies regarding the conduct, communication, and oversight of dual use research and research results, as requested.
- Advise on the Federal Select Agent Program, as requested.
- Address any other issues as directed by the Secretary of HHS.

AGENCY OR OFFICIAL TO WHOM THE COMMITTEE REPORTS

The NSABB will advise the Secretary of the Department of Health and Human Services (HHS), the Director of the National Institutes of Health (NIH), and the heads of all Federal entities that conduct, support or have an interest in life sciences research.

SUPPORT

Management and support services for the NSABB will be provided by the Office of Science Policy (OSP), within the Office of the Director, NIH. HHS and NIH staff will hold security clearances at the level of Secret or higher, as needed, to provide support to the NSABB.

ESTIMATED ANNUAL OPERATING COSTS AND STAFF YEARS

The estimated annual cost for operating the Committee, including compensation and travel expenses for members, but excluding staff support, is $274,900. The estimated annual person-years of staff support required is 1.5 at an estimated cost of $156,637.

DESIGNATED FEDERAL OFFICER

The Director, NIH, will assign a full-time or permanent part-time NIH employee to serve as the Designated Federal Officer (DFO) of the NSABB. In the event that the DFO cannot fulfill the assigned duties of the NSABB, one or more full-time or permanent part-time NIH employees will be assigned these duties on a temporary basis.

The DFO will approve or call all of the NSABB and subcommittee meetings, prepare and approve all meeting agendas, attend all Committee and subcommittee meetings, adjourn any meetings when it is determined to be in the public interest, and chair meetings when directed to do so by the Director, NIH, or the Director, OSP.

ESTIMATED NUMBER AND FREQUENCY OF MEETINGS

Meetings of the full committee will be held approximately two times within a fiscal year, and may be convened on an as-needed basis, at the call of the NSABB Executive Director or DFO. Meetings of the NSABB will be open to the public except as determined otherwise by the Secretary of Health and Human Services (Secretary), in accordance with subsection (c) of section 552b of Title 5 U.S.C. Notice of all meetings will be given to the public. In the event a portion of a meeting is closed to the public, as determined by the Secretary, in accordance with the Government in the Sunshine Act (5 U.S.C. 522b(c)) and the Federal Advisory Committee Act, a report will be prepared which will contain, as a minimum, a list of members and their business addresses, the Committee's functions, dates and places of meetings,

and a summary of the Committee's activities and recommendations made during the fiscal year. A copy of the report will be provided to the Department Committee Management Officer.

DURATION

Continuing.

TERMINATION

Unless renewed by appropriate action, the NSABB will terminate two years from the date this charter is filed.

MEMBERSHIP AND DESIGNATION

The NSABB will consist of not more than 25 voting members, including the Chair. Members will be appointed by the Secretary, HHS, in consultation with the heads of Federal departments and agencies that conduct or support life science research. The Secretary, HHS, will designate the Chair. All members will hold security clearances at the level of Secret or higher. Voting members are Special Government Employees and as such serve in their individual capacity as subject matter experts. None of these members serve as Representatives.

Areas of expertise to be represented on the NSABB, may include but are not be limited to:
Molecular Biology/Genomics
Microbiology (Bacteriology)
Microbiology (Virology)
Clinical Infectious Diseases/Diagnostics
Laboratory Biosafety and Biosecurity
Public Health/Epidemiology
Health Physicist/Radiation Safety
Pharmaceutical Production
Veterinary Medicine
Plant Health
Food Production
Bioethics
National Security
Military Biodefense Programs and Military Medicine
Intelligence
Biodefense
Law
Law Enforcement
Academia
Scientific Publishing
Industry Perspective
NIH Recombinant DNA Advisory Committee Experience/Perspective
Public Perspective
IBC perspective
Export Controls

There may be non-voting ex officio members from each of the following Federal entities:

- Executive Office of the President
- Department of Health and Human Services
- Department of Energy
- Department of Homeland Security
- Department of Veterans Affairs
- Department of Defense
- Department of the Interior
- Environmental Protection Agency
- Department of Agriculture
- National Science Foundation
- Department of Justice
- Department of State
- Department of Commerce
- Intelligence Community
- National Aeronautics and Space Administration
- Others as appropriate

Voting members will be invited to serve for overlapping terms of up to four years; terms of more than two years are contingent upon the renewal of the NSABB's Charter by appropriate action prior to its expiration. A voting member's term may be extended until a successor has been appointed.

A quorum for the NSABB and each of its subcommittees will consist of a majority of the appointed members eligible to vote. The nonvoting agency representatives will not be counted in calculating a quorum. Of the voting members, any who are recused from participating in an action on a particular issue, (e.g., due to a conflict of interest), will not be counted in calculating the quorum. All votes relating to any review of a recommendation by the NSABB will be open to the public unless the meeting has been closed to the public in accordance with the Government in the Sunshine Act and the Federal Advisory Committee Act.

SUBCOMMITTEES

As necessary, subcommittees and ad hoc working groups may be established by the NSABB Executive Director or DFO to perform functions within the Committee's jurisdiction. The advice/recommendations of the subcommittee/working group must be deliberated by the parent advisory committee. A subcommittee may not report directly to a Federal official unless there is statutory authority to do so.

Subcommittee membership may be drawn in whole or in part from the parent advisory committee. All subcommittee members may vote on subcommittee actions and all subcommittee members count towards the quorum for a subcommittee meeting. Ad hoc consultants do not count towards the quorum and may not vote. The Department Committee Management Officer will be notified upon establishment of each standing subcommittee and will be provided information on its name, membership, function, and estimated frequency of meetings.

RECORDKEEPING

Meetings of the Committee and its subcommittees will be conducted according to the Federal Advisory Committee Act, other applicable laws and Department policies. Committee and subcommittee records will be handled in accordance with General Records Schedule 6.2, Federal Advisory Committee Records, or other approved agency records disposition schedule. These records will be available for public inspection and copying, subject to the Freedom of Information Act, 5 U.S.C. 552.

The National Academies of
SCIENCES • ENGINEERING • MEDICINE

The **National Academy of Sciences** was established in 1863 by an Act of Congress, signed by President Lincoln, as a private, nongovernmental institution to advise the nation on issues related to science and technology. Members are elected by their peers for outstanding contributions to research. Dr. Ralph J. Cicerone is president.

The **National Academy of Engineering** was established in 1964 under the charter of the National Academy of Sciences to bring the practices of engineering to advising the nation. Members are elected by their peers for extraordinary contributions to engineering. Dr. C. D. Mote, Jr., is president.

The **National Academy of Medicine** (formerly the Institute of Medicine) was established in 1970 under the charter of the National Academy of Sciences to advise the nation on medical and health issues. Members are elected by their peers for distinguished contributions to medicine and health. Dr. Victor J. Dzau is president.

The three Academies work together as the **National Academies of Sciences, Engineering, and Medicine** to provide independent, objective analysis and advice to the nation and conduct other activities to solve complex problems and inform public policy decisions. The Academies also encourage education and research, recognize outstanding contributions to knowledge, and increase public understanding in matters of science, engineering, and medicine.

Acknowledgments

This workshop summary has been reviewed in draft form by individuals chosen for their diverse perspectives and technical expertise. The purpose of this independent review is to provide candid and critical comments that will assist the institution in making its published workshop summary as sound as possible and to ensure that the summary meets institutional standards for objectivity, evidence, and responsiveness to the study charge. The review comments and draft manuscript remain confidential to protect the integrity of the process. We wish to thank the following individuals for their review of this summary:

Thomas W. Armstrong, TWA8HR Occupational Hygiene Consulting, LLC
Harvey Fineberg, Gordon and Betty Moore Foundation
Matthew Frieman, University of Maryland
Diane E. Griffin, Johns Hopkins Bloomberg School of Public Health
Charles Haas, Drexel University
Gregory Koblentz, George Mason University
Peter Palese, Icahn School of Medicine at Mount Sinai
David Relman, Stanford University
Robert Webster, St. Jude Children's Research Hospital

Although the reviewers listed above have provided many constructive comments and suggestions, they did not see the final draft of the workshop summary before public release. The review of this summary

was overseen by Ellen Wright Clayton, Vanderbilt University, and Michael J. Imperiale, University of Michigan. They were responsible for making certain that an independent examination of this summary was carried out in accordance with institutional procedures and that all review comments were carefully considered. Responsibility for the final content of this summary rests entirely with the rapporteurs and the institution.

1

Introduction

On March 10-11, 2016, the National Academies of Sciences, Engineering, and Medicine held a public symposium on potential U.S. government policies for the oversight of gain-of-function (GOF) research.[1] This was the Academies' second meeting held at the request of the U.S. government to provide a mechanism to engage the life sciences community and the broader public and solicit feedback on optimal approaches to ensure effective federal oversight of GOF research as part of a broader U.S. government deliberative process. Approximately 125 people attended the event in person, while more than 200 others watched the webcast.[2]

The first symposium, held in December 2014, examined the underlying scientific and technical questions surrounding the potential risks and

[1] As described in the Draft Working Paper of the National Science Advisory Board for Biosecurity, "the phrase 'gain-of-function research' has become synonymous with certain studies that enhance the ability of pathogens to cause disease. However, gain-of-function studies, as well as loss-of-function studies, are common in molecular and microbiology and form the foundation of microbial genetics. Changes to the genome of an organism, whether naturally occurring or directed through experimental manipulations in the laboratory, can manifest as altered phenotypes as biological functions are lost or gained. Such loss- and gain-of-function experiments allow investigators to understand the complex nature of host-pathogen interactions that underlie transmission, infection, and pathogenesis and can help attribute biological function to genes and proteins. The term 'gain-of-function' is generally used to refer to changes resulting in the enhancement or acquisition of new biological functions or phenotypes" (NSABB, 2015a: 7).

[2] The archived webcast, the presentation slides, and a complete transcript of the symposium are available on the project website at http://dels.nas.edu/Upcoming-Event/Gain-Function-Research-Second/AUTO-9-61-70-Q?bname=bls.

benefits of GOF research involving pathogens with pandemic potential (NRC, 2015).[3]

The second symposium focused on discussion of the draft recommendations regarding GOF research of the National Science Advisory Board for Biosecurity's (NSABB's) Working Group (WG). The recommendations are contained in a draft paper, which was released in December 2015 and discussed at an NSABB meeting on January 7-8, 2016 (NSABB, 2015a).[4] It also included discussion of a formal risk and benefit assessment (RBA) commissioned to inform the NSABB's work (Gryphon Scientific, 2015) and sessions devoted to current U.S. policy and the international developments that provide essential context for U.S. decisions. The public symposium did not attempt to develop consensus recommendations, but rather sought individual perspectives and robust discussion to inform the development of the NSABB's final recommendations. The Statement of Task for the symposium may be found in Box 1-1.

This report has been prepared by the rapporteurs as a factual summary of what occurred during the symposium. The planning committee's role was limited to organizing and convening the workshop. The views contained in the report are those of individual workshop participants and do not necessarily represent the views of all workshop participants, the planning committee, or the Academies. The report offers a summary of the key issues and ideas identified during the symposium, but it offers no consensus conclusions or recommendations and is intended to reflect the discussions during the meeting. In order to be as responsive to the charge as possible, it is organized thematically rather than chronologically so that ideas raised at various points in the symposium are grouped together. A complete transcript that provides additional information about the contents of the presentations and discussions is available on the project website.[5]

OPENING REMARKS

The symposium was opened by Ralph J. Cicerone, president of the National Academy of Sciences (NAS). His remarks reflected on the long

BOX 1-1
Statement of Task

An ad hoc committee established by the National Research Council (NRC)[a] will organize two public symposia. The first symposium was held on December 15-16, 2014, and included discussion of the following topics:

- Principles important for, and key considerations in, the design of risk and benefit assessments of gain-of-function (GOF) research.
- Potential benefits of the research, including generating new scientific knowledge about viruses with pandemic potential, informing public health responses to a potential pandemic, supporting surveillance efforts to identify possible pandemic strains and provide more time for preparedness, and facilitating the development of vaccines and antiviral therapeutics.
- Potential risks associated with the research, in particular those related to biosafety and biosecurity.
- Alternative methods that may be employed to yield similar scientific insights and/or potential benefits, while reducing potential risks.

The second symposium—the focus of this task—to be held in early 2016, will focus on discussions of the National Science Advisory Board for Biosecurity (NSABB) draft recommendations regarding GOF research. This meeting will also include discussions of the results of the commissioned risk–benefit assessment as well as risk interpretation and analysis to inform decision making. This symposium will provide a mechanism to both engage the life sciences community as well as solicit feedback on optimal approaches to ensure effective federal oversight of GOF research. Of note, the public symposium should not include the development of consensus recommendations, but rather should elicit individual perspectives and robust discussion on the topics described above. Discussions at this symposium will inform the development of the NSABB's final recommendations.

The committee appointed by the NRC to organize and plan the second symposium will develop the symposium agenda, select and invite speakers and discussants, and moderate the discussions. Invited attendees should have a diverse range of perspectives and expertise, including but not limited to public health, biosafety, public health surveillance, research, risk assessment experts, public policy makers, security, and drug and vaccine development; the agenda should also include experts from regions of the world where pathogens with pandemic potential are endemic and from regions of the world conducting GOF research on such pathogens. This 2-day symposium will be webcast and the presentations and background materials will be archived online.

[a] On July 1, 2015, the institutional designation became the National Academies of Sciences, Engineering, and Medicine.

history of the NAS's engagement with the complexities of balancing the risks and benefits of science and technology. Providing a neutral forum in which to discuss the scientific underpinnings of complex and controversial topics is one of the major missions of the Academies, and he urged participants to engage fully in the discussions over the two days of the symposium.

Margaret Hamburg, Foreign Secretary of the National Academy of Medicine, then discussed the evolution of oversight of so-called dual use research in the life sciences, from the 2004 report on *Biotechnology Research in an Age of Terrorism* to the current GOF discussions (NRC, 2004).[6] Dr. Hamburg highlighted the role of the Academies in providing science advice to government. She indicated the importance of the GOF debate and the international nature of the issues and diseases involved. Dr. Hamburg noted that while the discussions at the symposium were focused on advice for the U.S. government, they would have implications for the global research enterprise. She underscored the importance of the symposium and its role in building on a wide range of earlier discussions on policy frameworks and approaches to addressing GOF research. This meeting, according to Dr. Hamburg, was an opportunity to look at those frameworks and approaches and identify desirable next steps. She identified a need to develop a strategic approach to support scientific progress while addressing the impacts for our societies.

Jo Handelsman from the White House Office of Science and Technology Policy believed this to be a landmark meeting, one that could direct future policy in important ways. She noted that the White House has focused on issues around GOF research for 18 months and recognizes the need to keep life sciences vibrant but also to protect safety and security across the globe. Officials had become engaged because of concerns around the creation of new pathogens, especially those with pandemic potential. The White House has also worked to address safety incidents at laboratories that raised public concerns over work with such pathogens (Holdren and Monaco, 2014). In response to these concerns, in October 2014 the White House announced a deliberative process and, along with it, a pause on federal funding for certain types of GOF research (White House, 2014a). Dr. Handelsman highlighted the importance of key exceptions to the funding pause to enable necessary emergency research to continue.

The NSABB was asked to draft recommendations for a conceptual approach for dealing with GOF research that would then be made available for public comment. As mentioned above, the Academies were asked

[6] In this context, "dual use" refers to the dilemma that "the same technologies can be used legitimately for human betterment and misused for bioterrorism" (NRC, 2004: 1).

to convene two public meetings to facilitate a broad discussion of all the relevant issues: one to review technical developments, and a second to discuss the draft recommendations prepared by the NSABB as well as policy options for GOF. Dr Handelsman noted that the NSABB's draft recommendations would be revised in light of the discussions at this symposium and in line with the public input they have received. Following this, an interagency process led by the Office of Science and Technology Policy will produce a policy that will provide federal oversight for GOF research and replace the funding pause.

Carrie Wolinetz from the National Institutes of Health began her remarks by stating that a robust life sciences research endeavor is critical to promoting public health and well-being in light of evolving threats posed by microbial pathogens. This endeavor will entail a certain amount of risk, she noted, requiring a thoughtful approach to reducing risk while taking advantage of the broad range of benefits. She commented that GOF research was a fundamental scientific tool to:

- Help define the nature of host–pathogen interactions;
- Enable assessment of the pandemic potential of emerging infectious agents;
- Inform public health and preparedness efforts; and
- Further medical countermeasure development.

Dr. Wolinetz stated that some GOF experiments had raised safety and security concerns about whether they could result in engineered pathogens capable of causing a pandemic if accidentally or deliberately released. There was also concern that information describing their development could be used by those with malign intent to cause harm through a deliberate release.

Dr. Wolinetz described the GOF deliberative process (see Figure 1-1). She recalled that the deliberative process included a pause in funding for GOF research involving influenza viruses and Middle East respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome coronavirus (SARS-CoV).[7] She highlighted the role that had been

[7] "New USG [U.S. government] funding will not be released for gain-of-function research projects that may be reasonably anticipated to confer attributes to influenza, MERS, or SARS viruses such that the virus would have enhanced pathogenicity and/or transmissibility in mammals via the respiratory route. The research funding pause would not apply to characterization or testing of naturally occurring influenza, MERS, and SARS viruses, unless the tests are reasonably anticipated to increase transmissibility and/or pathogenicity. In parallel, we will encourage the currently-funded USG and non-USG funded research community to join in adopting a voluntary pause on research that meets the stated definition" (White House, 2014a: 2).

played by the NSABB and recalled that it had been charged to advise on the design, development, and conduct of a risk–benefit assessment of GOF studies as well as to provide formal recommendations to the U.S. government on the conceptual approach to the evaluation of proposed GOF studies. During the process, the NSABB had also acted as a convening body. Dr. Wolinetz noted that the NSABB had received many valuable inputs to assist it in its work, including the report from the first Academies GOF symposium (NRC, 2015), the risk and benefit assessment conducted by Gryphon Scientific (Gryphon Scientific, 2015), and the ethics report commissioned from Michael Selgelid (Selgelid, 2015). Dr. Wolinetz concluded by noting that more input was being sought, for example, through the discussions at this symposium.

2

The Draft National Science Advisory Board for Biosecurity Policy Framework, the Risk and Benefit Assessment, and Insights for the Policy Process

OVERVIEW OF THE NATIONAL SCIENCE ADVISORY BOARD FOR BIOSECURITY DRAFT WORKING PAPER

Samuel Stanley, the chair of the National Science Advisory Board for Biosecurity (NSABB), highlighted the valuable role played by the National Academies of Sciences, Engineering, and Medicine's first symposium on gain-of-function (GOF) research in the deliberations of the NSABB's Working Group on GOF Issues (hereafter, NSABB WG), in particular during the development of its Draft Working Paper and recommendations. Dr. Stanley reviewed the activities undertaken by the NSABB since the start of the deliberative process. He reviewed the charge to the NSABB and highlighted the outputs produced to date, including *Framework for Conducting Risk and Benefit Assessments of Gain-of-Function Research* in May 2015 (NSABB, 2015b) and *Working Paper Prepared by the NSABB Working Group on Evaluating the Risks and Benefits of Gain-of-Function Studies to Formulate Policy Recommendations* in December 2015 (NSABB, 2015a).

Dr. Stanley introduced the NSABB WG's Draft Working Paper, noting that it included guiding principles for NSABB deliberations; analysis and interpretation of the formal risk and benefit assessment (RBA); consideration of ethical values and decision-making frameworks; analysis of the current policy landscape and potential policy options; preliminary findings from the NSABB WG's analyses; draft recommendations for the NSABB's consideration; and a number of important questions for further consideration. He reviewed key inputs into the work of the NSABB WG.

Dr. Stanley provided some reflections on the RBA prepared by Gryphon Scientific (Gryphon Scientific, 2015), describing it as rigorous and comprehensive and representing a monumental amount of work. The scope of the RBA addressed biosafety risks and biosecurity risks as well as benefits from GOF research. The study had allowed the NSABB to understand the different risks associated with research involving relevant pathogens and certain GOF experiments. It had helped them to identify and distinguish GOF studies that raise significant concerns from those that do not. Dr. Stanley indicated it assisted in identifying and evaluating the potential benefits of GOF studies and in comparing the potential benefits derived from GOF studies to those that may be achieved through alternative approaches.

Drawing on the ethics report prepared by Michael Selgelid (Selgelid, 2015), Dr. Stanley highlighted a number of important values to consider when evaluating research proposals involving GOF studies as well as when establishing mechanisms to review and/or make funding decisions about them. These included both substantive values (such as non-malfeasance, beneficence, social justice, respect for persons, scientific freedom, and responsible stewardship) and procedural values (such as public participation and democratic deliberation, accountability, and transparency).

He noted that there are multiple policies and frameworks already in place for managing risks during the research lifecycle (see Figure 2-1). These include reviews of the scientific merit of proposed research; measures for biosafety oversight, such as the *Biosafety in Microbiological and Biomedical Laboratories* manual (CDC and NIH, 2007) and the *NIH Guidelines for Research Involving Recombinant or Synthetic Nucleic Acid Molecules* (NIH, 2013); the Federal Select Agent Program; the U.S. government policies for federal and institutional oversight of life sciences dual use research of concern (White House, 2012, 2014b); the Department of Health and Human Services framework for guiding funding decisions about certain GOF studies with highly pathogenic avian influenza (HHS, 2012); and measures that relate to sharing and communicating scientific findings and research products. Dr. Stanley noted that the success of these measures depends on effective compliance and implementation. He noted that there were different levels of oversight depending on what pathogen was involved and what was being done with it.

Dr. Stanley then summarized the key findings and recommendations from the NSABB WG's Draft Working Paper. The five key findings are:

1. There are many types of GOF studies and not all of them have the same level of risks. Only a small subset of GOF studies—GOF studies of concern—entail risks that are potentially significant enough to warrant additional oversight;
2. The U.S. government has effective policy frameworks in place for managing risks associated with life sciences research (see Figure 2-1).

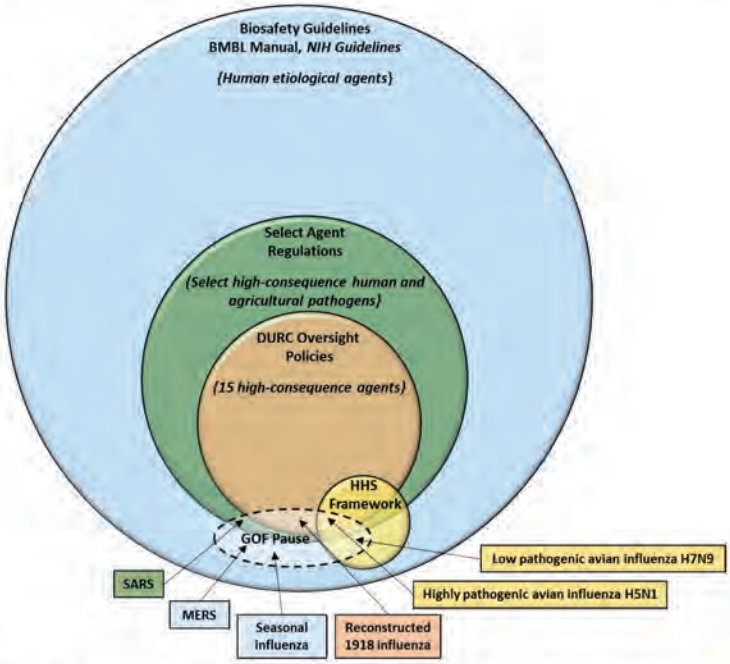

FIGURE 2-1 U.S. government policy frameworks for managing risks associated with life sciences research.
NOTE: BMBL = *Biosafety in Microbiological and Biomedical Laboratories*; DURC = dual use research of concern; GOF = gain-of-function; HHS = Department of Health and Human Services; MERS = Middle East respiratory syndrome; NIH = National Institutes of Health; SARS = severe acute respiratory syndrome.
SOURCE: National Science Advisory Board for Biosecurity, 2015a: 27.

There are several points throughout the research life cycle where, if the policies are implemented effectively, risks can be managed and oversight of GOF studies could be applied;

3. Oversight policies vary in scope and applicability, therefore, current oversight is not sufficient for all GOF studies that raise concern;
4. There are life sciences research studies that should not be conducted on ethical or public health grounds if the potential risks associated with the study are not justified by the potential benefits. Decisions about whether GOF research of concern should be permitted will

entail an assessment of the potential risks and anticipated benefits associated with the individual experiment in question. The scientific merit of a study is a central consideration during the review of proposed studies but other considerations and values are also important; and

5. The biosafety and biosecurity issues associated with GOF studies are similar to those issues associated with all high containment research, but a small subset of GOF studies have the potential to generate strains with high and potentially unknown risks. Managing risks associated with all high containment research requires Federal-level oversight, institutional awareness and compliance, and a commitment by all stakeholders to safety and security. Biosafety and biosecurity are international issues requiring global engagement. (NSABB, 2015a: 3-4)

The NSABB WG's Draft Working Paper also includes four recommendations:

1. Research proposals involving GOF studies of concern entail the greatest risks and should be reviewed carefully for biosafety and biosecurity implications, as well as potential benefits, prior to determining whether they are acceptable for funding. If funded, such projects should be subject to ongoing oversight at the federal and institutional levels;
2. In general, oversight mechanisms for GOF studies of concern should be incorporated into existing policy frameworks. The risks associated with some GOF research of concern can be identified and adequately managed by existing policy frameworks if those policies are implemented properly. However, the level of oversight provided by existing frameworks varies by pathogen. For some pathogens, existing oversight frameworks are robust and additional oversight mechanisms should generally not be required. For other pathogens, existing oversight frameworks are less robust and may require supplementation. All relevant policies should be implemented appropriately and enhanced when necessary to effectively manage risks;
3. The risk-benefit profile for GOF studies of concern may change over time and should be re-evaluated periodically to ensure that the risks associated with such research is adequately managed and the benefits are being realized.
4. The U.S. government should continue efforts to strengthen biosafety and biosecurity, which will foster a culture of responsibility that will support not only the safe conduct of GOF research of concern but of all research involving pathogens. (NSABB, 2015a: 4-5)

A key issue related to the first finding and recommendation is the question of what constitutes "GOF studies of concern." As Dr. Stanley explained:

> GOF research of concern would be a study that can be anticipated to generate a pathogen that is, one, highly transmissible in a relevant mammalian model, two, highly virulent in a relevant mammalian model, and three, is likely more capable of being spread among human populations than currently circulating strains of the pathogen. The first two characteristics are intended to involve the concept of the threshold. That is, the generated pathogen would need to be highly transmissible and highly virulent. Studies of pathogens with moderate virulence and transmissibility entail risks of course, but in general, those risks can be managed through existing mechanisms. The third criterion is intended to capture the concept of pandemic potential. That is, a pathogen could spread rapidly among human populations, either because there's no population immunity, no available counter-measures, or for some other reason. (Stanley, 2016)

The question of the appropriate criteria for defining GOF studies of concern was a recurring theme in subsequent discussions.

Dr. Stanley went on to explain that the NSABB WG had also identified a number of principles for guiding funding decisions related to GOF studies of concern (see Box 2-1).

To further assist in determining how such arrangements might function in practice, the NSABB WG had continued to develop the conceptual approach for the review, funding, and oversight of GOF studies of concern, including a new diagram (see Figure 2-2), which Dr. Stanley presented at the symposium. It includes activities to be undertaken at the institutional and federal levels and details what additional steps would be required for GOF studies of concern. He added that, as discussed at the NSABB's January meeting and in the NSABB WG's Draft Working Paper, the NSABB had highlighted a number of questions that needed further consideration and input (NSABB, 2015a: 46). He said that the NSABB WG was also considering a new question: "What type of body should be tasked with the high-level review of GOF research of concern. Would a FACA-like[1] committee be desirable, or as now envisioned by NSABB, can such reviews be accomplished by federal agencies, or other groups internal to the United States government?"

Dr. Stanley concluded by saying that the NSABB would continue working on its recommendations, with plans for a meeting scheduled for May 24, at which the final report would be discussed and possibly voted

[1] "The Federal Advisory Committee Act [FACA] was enacted in 1972 to ensure that advice by the various advisory committees formed over the years is objective and accessible to the public. The Act formalized a process for establishing, operating, overseeing, and terminating these advisory bodies" (General Services Administration, http://www.gsa.gov/portal/category/21242).

BOX 2-1
NSABB Principles to Guide Funding Decisions for Gain-of-Function Research of Concern

The following principles should guide the review of and funding decisions about research proposals anticipated to involve GOF research of concern:

i. The research proposal has been evaluated by a peer-review process and determined to be scientifically meritorious and has been assessed to be likely to exert a sustained, powerful influence on the research field(s) involved.
ii. An assessment of the overall potential risks and benefits associated with the project determines that the potential risks compared to the potential benefits are justified.
iii. There are no feasible, equally efficacious alternative methods to address the same scientific question in a manner that poses less risk than does the proposed approach.
iv. The investigator and institution proposing the research have the demonstrated capacity to carry it out safely and securely.
v. The research information is anticipated to be broadly and legally shared in order to realize its potential benefits to global health.
vi. The research will be supported through funding mechanisms that include appropriate oversight of (a) all aspects of the research including its conduct, (b) the sharing of data and materials, and (c) the communication of the research.
vii. The proposed research is ethically justifiable.

SOURCE: NSABB, 2015a: 43.

on. He encouraged the participants to continue to submit comments to the NSABB and to take an active role in the symposium discussions.

Harvey Fineberg, chair of the Symposium Planning Committee, then moderated an open discussion of the NSABB WG's Draft Working Paper. In his introductory remarks, Dr. Fineberg highlighted the importance of determining what does, or should, qualify as GOF studies of concern and the subset of research that may warrant additional oversight. He recalled the three characteristics identified by the NSABB WG and stressed the importance of defining the threshold between research of concern and other studies. He commented that the proposed definition did not take into account the starting point of virulence, transmissibility, or resistance of the pathogen. "If you have a very resistant organism that is very virulent if contracted, and all you want to do is to test whether the function of transmissibility could be enhanced, why would that be less of concern than starting with a less virulent, less resistant, less transmissible organism, and trying to produce increased function along all three

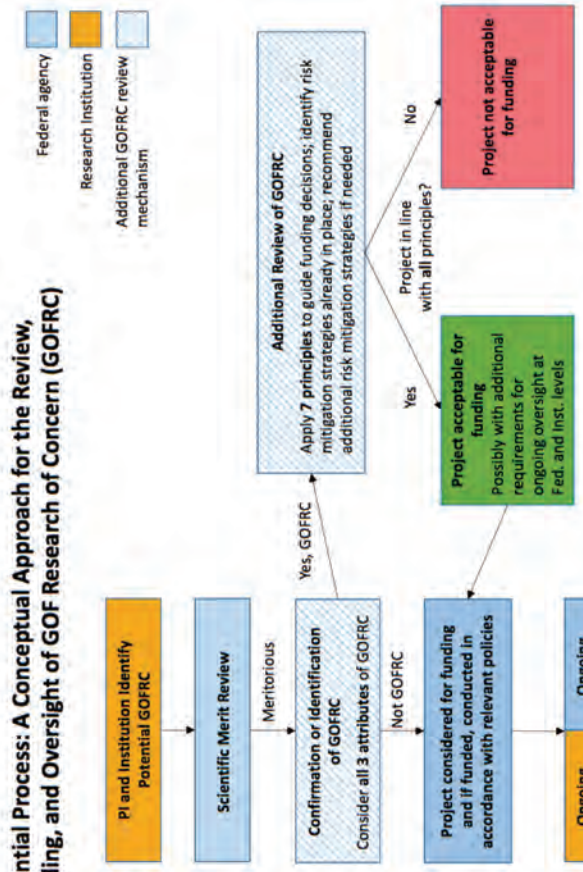

FIGURE 2-2 A conceptual approach for the review, funding, and oversight of gain-of-function research of concern.
NOTE: GOF = gain-of-function; PI = principal investigator.
SOURCE: Stanley, 2016.

dimensions?" He suggested that conceptually it might make more sense to think about "zones" of GOF research where concerns arise, because any combination of the three, or any one, two, or three, leads to a zone of concern outside of what the native organism represents (Fineberg, 2016).

Dr. Fineberg commented that the research enterprise is generally positive because it reveals truths of nature. But there could be a class of investigations that provoke scientific, ethical, or social concerns. In such cases, he felt, the burden of proof as to the value of a specific piece of research would move to those wanting to pursue it.

In conclusion, he added to Margaret Hamburg's comments, noting that, although the NSABB was focused on recommendations for U.S. policy, this was intrinsically a global challenge. He expressed the hope that during the symposium participants would consider the issues related to the development of a global regime to manage this class of research of concern, in addition to and beyond any national regime.

Discussion

Joseph Kanabrocki from the University of Chicago and Kenneth Berns from the University of Florida, co-chairs of the NSABB WG, joined Dr. Stanley on stage for the discussion.

The discussion that followed highlighted several themes from the presentations. The scope of assessing risks and benefits was explored, with questions raised by George Gao from the Chinese Academy of Sciences and the Chinese Center for Disease Control and Prevention about why there was comparatively little focus on loss-of-function experiments, given the difficulty of predicting which method would reduce, or increase, or enhance a virus's virulence or transmissibility. More broadly, Keiji Fukuda from the World Health Organization noted connections to other issues in which life sciences research lies at the heart of safety or security concerns, such as food security or genetically modified organisms. He highlighted the importance of engaging with access and benefit-sharing regimes.

Alternative approaches to tying increased oversight to funding were discussed. Some participants felt that direct regulatory approaches would be preferable. A review of different policy options from a recently published commentary was presented by Thomas Inglesby from the Center for Health Security, University of Pittsburgh Medical Center (UPMC), that included lifting the moratorium on GOF research; seeking an international consensus; securing national and international agreement to restrict the performance of GOF studies of concern; designating a board; establishing clear red lines for GOF studies of concern; and requiring the purchase by research institutions of specific liability insurance policies (Lipsitch et al., 2016). Megan Palmer from Stanford University reflected that several

of the questions identified by the NSABB WG as requiring further consideration corresponded to some of the tasks given to the NSABB by the White House. She also asked the NSABB WG to provide key lessons on the limitations of expertise or limitations in the process that might be fed into broader or future discussions on the oversight of life science research.

The importance of international collaboration was stressed and the potential for those wishing to undertake GOF studies of concern to relocate to less restrictive environments was noted by Abdulaziz Alagaili from King Saud University in Saudi Arabia. He also argued that any oversight frameworks should apply to the private sector as well as academia. Piers Millett from Biosecure suggested that an international component should be a significant aspect of future work, including the allocation of necessary resources; a mandate for long-term, sustained engagement; and genuine two-way conversations (rather than the presentation of a finalized solution). He also suggested that any international discussions should be co-hosted by relevant health and security entities to prevent perceptions of bias.

The outcomes from discussions held in other countries about GOF research were highlighted. Filippa Lentzos from King's College London, for example, in a comment made via the Web, noted findings from these discussions of the

- Lack of clear and convincing justifications for GOF studies of concern;
- Role of personal or institutional interests in agenda setting;
- Global dimension of GOF research of concern and the need for an international solution;
- Potential for accidents, abuse, and malpractice, and the intricate relationship between trust and accountability;
- Instability of political contexts and changing security environments, and the need for transparency in biodefense-related research; and
- Need for clear red lines on the most dangerous GOF experiments that apply to the public, private, and military sectors.

She also raised the issue of how to ensure that the lay public's voice is heard and incorporated into the decision-making process around GOF of concern research.

Another participant, Catherine Rhodes from the University of Cambridge, recalled a recent meeting in the United Kingdom in which influenza researchers indicated an interest in developing international approaches to the oversight of relevant research but feared any such process becoming dominated by existing U.S. policy discussions.

On the question of how to define "GOF studies of concern," some participants objected to requiring that all three of the characteristics recommended by the NSABB WG be met. Dr. Millett felt that the threshold for risk requiring additional oversight had been set too high and that any research that would be expected to produce a pathogen with any two of the characteristics should be considered for additional oversight. In this respect, Marc Lipsitch from Harvard University noted that the original GOF experiments that prompted the international controversy were initially believed to have met only two of these criteria, and eventually met only one. Thus, those experiments would not be subject to any of the oversight provisions under discussion. He and Dr. Inglesby argued that the third criterion was superfluous and that only issues of transmissibility and virulence need be considered. Dr. Lipsitch cited the original White House charge (White House, 2014a), public comments submitted to the NSABB by the Infectious Disease Society of America (IDSA, 2016), and "common sense" in support of his argument. John Steel from Emory University raised technical questions about how to measure these characteristics; for example, what does "highly" transmissible mean? He also cited the shortcomings of animal models to approximate transmissibility and called for additional guidance on how to make such decisions in practice.

The discussion also included a number of other specific reflections on the NSABB WG's Draft Working Paper and its recommendations

- Dr. Inglesby highlighted how important it was that any relevant regulations or other measures governing GOF studies of concern apply anywhere relevant research is being conducted, regardless of whether the laboratory receives federal funds or whether it is found in the public or private sectors.
- The value of the NSABB making its recommendations broad enough to fit GOF studies of concern with any pathogen, rather than just those covered by the moratorium, was noted by Dr. Millett. He also suggested that any characterization of GOF studies of concern should not be based upon taxonomy but instead focus on functional characteristics as contained in the draft definition.
- Dr. Selgelid from Monash University in Australia raised the possibilities of making oversight arrangements progress along a spectrum rather than being treated as binary. In such a model, a single risk threshold would not be established (above which research would be governed by specific oversight measures), but rather increasing levels of oversight would apply as the relative risk of the work increases. He also commented that, rather than first making a judgment about the scientific merit of a study and then assessing whether it raised GOF issues of concern, it might

be better to include considerations of risk at the earlier stage. If two studies show equal scientific merit and neither is considered of concern, then—other things being equal—would it be better to fund the less risky study if one cannot fund both?

- Questions as to the efficacy of the existing arrangement for addressing biosecurity information risks were raised by Dr. Inglesby and Dr. Millett, who encouraged further reflection on suitable oversight.
- Some participants, such as Dr. Millett, felt that bodies involved with assessing risks and benefits could not be housed within either the health or the security architecture but should be located inside a neutral agency.
- Questions about the interface between the proposed regulatory framework developed by the NSABB WG and existing arrangements for GOF experiments with specific agents, such as the one implemented by the National Institutes of Health (NIH), were raised by Nicholas Evans from the University of Pennsylvania. The ethics report also was discussed, with Dr. Evans suggesting that the scope of ethical issues related to GOF studies of concern was considerably broader than the scope of those included in the consideration of benefits in other areas, such as human subjects research. This, he suggested, would seem to increase the challenges in suitably reflecting potential benefits of GOF studies of concern.

Dr. Fineberg began the period of taking responses from the NSABB members by welcoming comments on any issue but said he hoped that they would reflect in particular on the "core question of what qualifies as being of concern." He noted that there had been a variety of viewpoints expressed about the necessity of meeting all three criteria, the implications of thresholds versus a spectrum, and the question he had raised earlier of whether the starting point could enough to make research meeting only one criterion "of concern." Dr. Kanabrocki responded by clarifying that the NSABB had not changed its thinking, as some had suggested, about the third criterion. The NSABB WG had recognized that there was some misinterpretation of the original language to limit the criteria to only resistance to countermeasures. Instead the intent is to capture the broader question of pandemic potential. Dr. Berns added that he emphasized "what's important is what you wind up with," that is, the potential for a pandemic and this led to the question of whether or not there were existing defense mechanisms. He also commented on the difficulty of predicting the consequences of research and the challenges in attempting to quantify such risks. Dr. Stanley commented that the issue was whether

the research could create risk significantly above the existing risk for that pathogen. Again, this tied to the questions of natural immunity or countermeasures.

In response to other questions and comments, Drs. Stanley, Kanabrocki, and Berns acknowledged the importance of the issues that had been raised, and they commented that the NSABB had struggled, for example, with the question of whether to offer broad recommendations or the more specific guidance for which some participants were calling. Dr. Berns commented that, even more than the definition, he thought the NSABB WG had struggled with the level at which the decision would be made. Should the final decision be made inside the government or by an outside group, such as a FACA committee? Efficiency might suggest handling the decision inside the government, but the public interest in transparency would argue strongly for a FACA committee. They also noted that, although the NSABB was tasked to make recommendations for the U.S. government, they recognized the importance of the international dimensions of the issue. Dr. Stanley thought all the members of the NSABB, as well as its sponsors, believed that it was necessary to "strive for a global solution here, and that some type of harmonization essentially of these processes would be extraordinarily valuable." The process was definitely not completed and they welcomed the input the NSABB WG would receive during the 2 days of the symposium.

LESSONS FROM THE RISK AND BENEFIT ASSESSMENT

Charles Haas from Drexel University, a member of the Symposium Planning Committee, introduced the goals of the session. The details of the risk and benefit assessment (RBA) had already been reviewed in detail at the January 2016 NSABB meeting.[2] The purpose was therefore to build on those prior discussions to consider how risk assessment more broadly could serve the important roles that the NSABB's draft findings and recommendations, including its proposed conceptual approach for making decisions about GOF studies of concern, had given to judgments about risks and benefits.

Rocco Casagrande from Gryphon Scientific provided an overview of the RBA (Gryphon Scientific, 2015) as basic background for the session. The purpose of this 8-month study was to provide data on the risks and benefits associated with research on modified strains of influenza viruses

[2] The webcast of those discussions, along with copies of presentation slides and written public comments, are available at http://osp.od.nih.gov/office-biotechnology-activities/event/2016-01-07-130000-2016-01-08-220000/national-science-advisory-board-biosecurity-nsabb-meeting.

and the coronaviruses. The RBA had been divided into three major tasks, each of which required a distinct data collection and analysis approach: a quantitative biosafety risk assessment; a semi-quantitative biosecurity risk assessment; and a qualitative benefit assessment. Dr. Casagrande noted that the RBA was comparative; it determined the change in risk from research on GOF pathogens compared to research on wild type pathogens and identified the benefits to science, public health, and medicine afforded by GOF research compared to alternative research and innovations.

Dr. Casagrande presented key findings from the RBA. The biosafety risk assessment included a map of the series of events necessary for a laboratory incident to result in a pandemic. The probability of each event resulting in the next necessary event was determined. The RBA established that only a small minority of laboratory incidents with the most contagious influenza viruses would cause a local outbreak, and only a minority of those would lead to a global pandemic.

The published RBA had identified the pandemic strain of the 1918 H1N1 influenza virus as posing the greatest risk. However, subsequent information made available to Gryphon Scientific at the January NSABB meeting by Dr. Kanta Subbarao from NIH showing a high degree of cross protection afforded by exposure to the 2009 influenza against the 1918 influenza enabled a reassessment. Further analysis determined that the naturally circulating 1957 H2N2 influenza virus became the "riskiest" pandemic strain because its antigenic profiles would cause about 100 times more global cases, although it is only one-tenth as deadly as the 1918 strain.[3] As a result, it became the comparator against which other risks should be evaluated. The RBA also determined that the riskiest modified strain was a 1918 H1N1 strain altered to evade residual immunity or to be otherwise more transmissible.

Other key findings from the biosafety assessment included

- Manipulating GOF seasonal influenza strains at the BSL3 level may compensate for the increase in risk posed by the modified strains, largely because the extra system of respiratory protection decreases the risk of a laboratory acquired infection.
- Some of the manipulations that could theoretically increase risk may not be achievable or desirable. For example: (i) a strain that can overcome protective vaccination increases risk only if it can evade vaccine protection via immune modulation, not antigenic

[3] The details of the Gryphon Scientific analysis are available in supplemental material on its website: http://www.gryphonscientific.com/wp-content/uploads/2016/03/Supplemental-info%E2%80%93Protection-against-Infection-with-1918-H1N1-Pandemic-Strain.pdf. The final version of the report was released in April 2016 (Gryphon Scientific, 2016).

change; (ii) the scientific value of increasing the transmissibility of influenza virus beyond that of the most transmissible strains (or final titer beyond 1E8) is questionable and perhaps infeasible; (iii) there is no animal model of transmission for the coronaviruses, so manipulation of this trait is not currently achievable; and (iv) some estimates suggest that severe acute respiratory syndrome coronavirus (SARS-CoV) may already be more transmissible than was estimated in the RBA, in which case further manipulation would not affect risk.

The biosecurity risk assessment had two components: an assessment of the risks from acts targeting a laboratory; and security risks derived from the information generated by the studies. Key findings of the assessment of risks from acts targeting a laboratory included

- The traits that drive risk are similar when considering biosafety and biosecurity because the pathogens are transmissible. How the initial infections were caused is of little consequence once a local outbreak begins.
- Biosecurity events are often predicted to involve the covert infection of the public, so this type of an infection is much more likely to cause a global outbreak. By contrast, laboratory workers benefit from health surveillance and isolation protocols not available to the general public.
- To match the risk posed by biosafety incidents given a historical rate of laboratory acquired infections, a biosecurity event that covertly infects a member of the public must occur only once every 50-200 years. These events include theft of an infected animal, contaminated piece of equipment, or viral stock. Given the frequency with which these biosecurity events have happened, the RBA suggested that biosecurity be given as much consideration as biosafety.

The information biosecurity risk assessment analyzed "the risk that a malicious actor might misuse the information in publications describing GoF research" (Gryphon Scientific, 2015: 212). Key findings included

- Minimal information risk remains for GOF studies in influenza viruses because dual use methods have already been published.
- Significant information risk remains for GOF studies in the coronaviruses, but these studies are hampered by a lack of model systems.
- Information risk could easily be generated by research on other transmissible pathogens.

The benefits assessment identified GOF studies providing critical or unique benefits for both

- Influenza viruses, including studies that enhance viral growth from low titer; lead to evasion of residual or induced immunity; enhance virulence; enhance transmissibility; and lead to evasion of therapeutics in use and in development. And,
- Coronaviruses, including studies that alter host tropism; enhance virulence; and lead to evasion of therapeutics in development.

Dr. Casagrande highlighted a number of lessons learned during the execution of the RBA. He stated that the distinction between seasonal and pandemic flu is artificial because an old seasonal flu strain could become a new pandemic strain (as highlighted by 1957 H2N2 replacing 1918 H1N1 as the riskiest pandemic strain). He noted the lack of data on human reliability in life sciences laboratories in contrast to data from other well-researched sources such as the nuclear, chemical, and transportation industries. Those data show that human error is the most common cause of accidents. To use an example from the life sciences, it is more common for a lab worker not to use a powered air purifying respirator (PAPR) properly than for a PAPR to be defective. He also cited the difficulty posed by having no risk benchmark for work with wild type pathogens and the difficulty posed by restriction of the RBA to influenza and coronaviruses.

The RBA was then applied to a number of specific experiments, including those that

- Include virulence factors from 1918 H1N1 influenza in a 2009 H1N1 strain, which did not increase the probability that an outbreak escapes local control and indicated that global consequences scale linearly with case fatality rate.
- Aim to create antigenically distinct strains of a recently circulating seasonal influenza strain, which resulted in strains having a 2-3-fold increase in risk of escape, capable of inflicting 10 times more global deaths, resulting in a 20-30-fold increase in risk of infection. The meaning of this risk increase is difficult to interpret in the absence of standards for risk tolerance but suggests that more controls and measures should be taken to control infection risk from this modified pathogen than from the wild-type pathogen.

Dr. Casagrande also noted that bench researchers may not be familiar enough with the epidemiological properties of pathogens to properly characterize their strains. Guides or tools are needed to easily obtain

parameter values for wild type strains and, perhaps, to aid with the calculations.

A series of commentators provided reflections on the RBA. They were asked to consider

- What they know needs to occur, based on their prior experience in the context of policy making, to make use of the Gryphon Scientific analysis and other information.
- The potential value of risk–benefit analysis in making decisions on individual cases of proposed research projects rather than the role of a study intended to cover an entire class (i.e., GOF) of investigation, which was the purpose of the Gryphon Scientific analysis.

Louis (Tony) Cox from Cox Associates highlighted the value of attempts to quantify risk in the RBA (Cox, 2016). Dr. Cox also discussed risk management, or what to do about that risk, especially as it related to determining which proposals to fund. Dr. Cox highlighted the value of clearly defined decision rules and conditional decision rules, detailing the conditions that would need to be met before a proposal might be funded. Dr. Cox reflected that efforts to determine the maximum acceptable risk were not useful approaches in a GOF setting. He argued that both the context and the benefits needed to be taken into account and suggested that attempting to improve the risk–benefit profile may be a more suitable approach. Dr. Cox suggested that "arbitrary coherence"—accepting risks because they are less risky than those we already accept—was also not appropriate in a GOF context. He believed that benchmarks and precedents were not necessarily the most appropriate basis for decision making but supported gathering more information before making funding decisions, including on opportunity costs. He asserted that there is a need to learn from past experience and to make the decision-making process adaptive. Dr. Cox also identified a series of specific proposals for strengthening funding decisions on GOF studies of concern (see Box 2-2).

Kara Morgan from Battelle Memorial Institute reminded participants of the difficulty of decision making on low-probability, high-risk events. Dr. Morgan introduced a number of tools developed to assist in such situations and help match decision-making complexity to potential risk. She discussed three frameworks for decision making, describing the frameworks as part of a continuum, enabling their adaptation to different contexts (see Box 2-3).

Dr. Morgan concluded that decision making is a social process, not an analytical one. There is a need for a process to help move from analysis to a decision. She advised the symposium that decision frameworks, rules, and process were just as important as the analysis.

BOX 2-2
Proposals for Improved Funding Decision Making on Gain-of-Function Research of Concern

- A decision rule maps available information to decisions—specifically whether to fund, not to fund, to require modifications before funding, or to seek additional information on which to base a funding decision.
- The performance of a decision rule can be evaluated for a stream of simulated projects with specified risk, cost, benefit, and information/uncertainty characteristics and proposer response characteristics.
- If we know enough about GOF research to simulate realistic project proposals and decision rule performance, then simulation-optimization of decision rules can lead to better (higher-performing) individual project-funding decisions.
- Otherwise, eliminate dominated decision rules (e.g., risk matrices, simple additive scoring systems)

SOURCE: Cox, 2016.

Adam Finkel from the University of Pennsylvania set out five factors to strengthen risk–benefit analysis that should be integrated into the development of the policy framework for GOF studies of concern (see Box 2-4).

Dr. Finkel noted considerable differences in opinion among different risk estimates of GOF studies of concern. He argued that risk was not a binary state and this provided the potential for a hierarchy of decision rules. He also noted the importance of including justice and equity for those individuals affected by risk. Dr. Finkel commented that it becomes much harder to assess risk when uncertainties exist and they are uncorrelated. He also felt that it was necessary to do a better job of communicating the benefits of GOF research. He called for further efforts to identify where the faults that lead to risk are occurring. He introduced a new study of existing best practices in regulatory excellence based on the concept of "listening, learning, and leading" developed through work in the Canadian energy sector (Coglianese, 2015).

Dr. Finkel discussed the importance of basic laboratory safety. He believed the best way to prevent accidents from infecting the population was to prevent them from infecting laboratory workers. Dr. Finkel concluded by encouraging the use of a more solution-focused risk–benefit analysis—where options are not restricted to a specific limited set of options—but one which focuses on the underlying policy need. He provided examples from sources of drinking water and synthetic biology. He cautioned that uncertainties rarely cancelled each other out in practice.

BOX 2-3
Different Models for Risk-Based Decision Making

Acceptable risk—In this model the risk is estimated along a spectrum. A boundary or threshold is set above which one decision would be taken and below which a different decision would be taken. The main challenge with this approach is derived from the innate uncertainty of science. While it is possible to mitigate this through the use of safety factors, it can still result with benefits not being taken into account. The process of determining where the boundary falls can also be challenging and past discussions on GOF have already demonstrated notable differences of opinion on this point.

Risk–benefit assessment—This is a two-factor analysis and builds on an understanding that societies are often prepared to tolerate some risk if they receive benefits in return. While this model does take benefits into account, to be fully effective, it is necessary to express both risks and benefits in comparable terms, preferably using the same metrics. This can often involve value judgments. A decision as to where the appropriate balance lies between risks and benefits is often subjective.

Deliberative criteria-based frameworks—This model allows the introduction of more factors. It enables the integration of different views through the use of criteria identified in advance of assessment. It can include both scientific contexts based upon observations and perceptions (such as facts, data, analytical results, assumptions, and uncertainties) and social contexts based on values (such as goals, objectives, priorities, concerns, ethical issues, non-observable criteria, policy decisions, and tradeoffs). This model is more resource intensive than the other approaches but is more collaborative.

SOURCE: Morgan, 2016.

BOX 2-4
Factors for Strengthening Risk–Benefit Analysis

1. Risk and benefit estimates should be balanced, quantitative, humble, explicit about value judgments, and channeled in service of a thoughtful decision rule.
2. Benefit estimates can be made commensurable with risk estimates, and should be communicated with equal care.
3. Purely risk-based prioritization is inferior to net-benefit prioritization.
4. Transparency in public engagement is important, but not as important as "apparency" (which provides information on rationale and motivations).
5. "Solution-focused" analysis of GOF and public choice may require wholly new institutional arrangements, not just incorporation into existing policy frameworks.

SOURCE: Finkel, 2016.

Discussion

The resulting discussion began by highlighting the importance of having good baseline data against which to measure risk: for example, through a national database or framework of laboratory near misses, accidents, or disclosures, as discussed by James Welch from the Elizabeth R. Griffin Foundation. Panelists noted that the U.S. government had already committed to develop such a database (U.S. Government, 2015: 4).[4] The need for additional resources to undertake focused research to fill data gaps was highlighted by Gigi Kwik Gronvall from the UPMC Center for Health Security. Shortages of data on benefits and risks were felt by several participants to apply to infectious disease research and emerging areas of life science research more broadly. The importance of tools to enable scientists to operate safely and securely on an ongoing basis was also noted by Dr. Gronvall. There was also a discussion, prompted by Allison Mistry from Gryphon Scientific, of the need to differentiate between conducting functional changes in wild type as opposed to research backbones or chassis. The value of including comparative risks in different chassis in definitions of GOF and GOF studies of concern was also explored.

Participants also considered the limits of comparing risks and benefits in this type of research. The discussion explored the challenges in suitably reflecting the potential public health benefits of research. Corey Meyer from Gryphon Scientific, who had led the benefits assessment portion of the RBA, made a number of comments. She said that although it may be possible, at least qualitatively, to compare the risks and benefits of research for public health, she was not sure that was true for the benefits of scientific knowledge. She also wanted to underscore that "while the risks of the research are immediate in that they are occurring at the time the research is being conducted, the benefits to public health will be realized in the future. And there is significant uncertainty in how long it will take for those benefits to be realized because translation of basic science research into public health benefits is complex and depends on many other factors."

Adam Finkel commented that there is a substantial literature on discounting and the time value of benefits on which one could draw. He thought the problem was not intractable and offered the example of climate change research, where he said there is a movement toward lower discount rates. In this area, "the future speaks more loudly than we

[4] The recommendation—"Establish a new voluntary, anonymous, non-punitive incident-reporting system for research laboratories that would ensure the protection of sensitive and private information, as necessary"—is one of the products of the Federal Experts Security Advisory Panel, whose report was made public in October 2015 (U.S. Government, 2015).

have allowed in the past." So that part is not at all intractable. He cited the example from Michael Selgelid's white paper of benefits in terms of expected lives saved.

Rocco Casagrande commented that the daunting part of assessing future benefits is not how much to discount potential lives saved but how to make an estimate of how likely it is that any scientific discovery will lead to a public health benefit. Tony Cox commented that it also depends on what other research is done. And Kara Morgan noted that even failed experiments may offer useful lessons. John Steel also noted that such research can help ameliorate disease events that happen infrequently but that potentially result in tens of millions of deaths.

Some participants, such as Marc Lipsitch, questioned the findings on the unique benefits of certain GOF research, suggesting that the knowledge could have been generated using alternative approaches. In his view, the net contribution of GOF research to knowledge on influenza viruses has been overstated. He also said that the knowledge about mutations and phenotypes identified by Fouchier and Kawaoka had already been identified in previous safe experiments. The confirmation that they were important in the GOF context was new, but he asserted that their utility for public health prediction was so far unproven. "So the net benefit for public health is much smaller than the net knowledge." Issues around identifying and ensuring sufficient oversight of dual use research more broadly were also discussed, including that, as life science and biotechnology tools are getting more powerful, the potential for their misuse for malign purposes might also increase. On the RBA, some participants, such as Piers Millett, reflected that the process of updating the risk comparator from the 1918 influenza strain to the H2N2 1957 pandemic strain was a practical example of the importance of the inclusion of the concepts of innate or acquired immunity against pathogens in the third set of characteristics proposed by the NSABB to define GOF studies of concern. He also suggested that the RBA was a missed opportunity to explore the international opportunity costs associated with different decisions on GOF studies of concern, from a moratorium on relevant research, through increased oversight, to taking no additional steps.

The shortcoming of existing arrangements in identifying and mitigating biosecurity information risks was noted by some participants, including Victoriya Krakovna from the Future of Life Institute, Dr. Millett, and Megan Palmer. They argued that these assessed risks were only low because the critical information had already been released into the public domain over the last decade. This led to questions about the efficacy of current arrangements to identify potential future biosecurity information risks, such as those for coronaviruses highlighted in the RBA. The value of encouraging comments and reflections on the RBA and associated

methodologies from a wider group including different types of expertise was also noted by Megan Palmer.

THE SCIENCE OF SAFETY AND THE SCIENCE OF PUBLIC CONSULTATION

Baruch Fischhoff from Carnegie Mellon University, a member of the Symposium Planning Committee, opened the session by explaining that there had been a successful session at the first Academies GOF symposium, which offered an introduction to the lessons from research into human factors, public consultation, and risk assessment to inform the preparations by NIH and the NSABB for the RBA. This year the planning committee had organized another session focused on the insights that social science research can offer about the design and implementation of federal oversight for GOF studies of concern. The panel included experts in organizational culture, human factors, and public consultation who would offer comments on the NSABB draft recommendations and specific suggestions for the ultimate choices to be made by the U.S. government.

Ruthanne Huising of McGill University introduced the insights about compliance with safety regulations in life science laboratories gained from past research in which she had taken part (see, e.g., Huising and Silbey, 2011). Since 2012 she had also been observing Canadian regulators design new biosafety and security regulations that went into force in December 2015 using an intensive public consultation process.

Dr. Huising discussed behavior and decision making as mediated by social organizations, which can include both formal social structures (such as organizations and families) and what she termed emergent systems of meaning ("culture"), which include norms, values, and assumptions. The incidents that led to the GOF deliberative process had provoked extensive discussions of the existing culture of life sciences laboratories as this affected safety and security. In these and similar discussions, the concept of culture is often treated as both the "problem" (a "lax culture" or "insufficient culture") and the "solution" ("build a culture of safety," "change the culture"). Culture, she argued, is often understood as a managerial tool. She described how concepts of culture can be applied to understand how laboratories approach and implement safety provisions.

Dr. Huising described how culture might be shaped through socialization processes. Beginning with graduate training, researchers are observing and learning how successful members of their field think, talk, and act. They learn how competent, respected members of the community behave, potentially through their attention to safety, security, and risk.

Safety cultures can be designed and Dr. Huising provided examples of the systems used by BP and Dow Chemicals. Such efforts tend to be

top down and centralized, she noted. They can be slow to develop and expensive, and they often ignore differences in interests and resources. She suggested that safety cultures can also emerge, resulting in multiple, heterogeneous cultures. Such change often occurs in response to shocks, with new values and norms emerging. This approach can be slow, but it is self-reproducing. Dr. Huising felt this model might be more suitable for the scientific endeavor, in part because it would better reflect the nature of the organizational structure of research laboratories.

The organizational structure of relevant institutions can also impact culture, Dr. Huising noted, with administrative and academic laboratory components operating with different logics. Academic administration is organized in ways that give it considerable similarities to the organization of regulatory and other government agencies. In contrast, the laboratories, at least in theory, operate through collegial governance and a democratic approach to organizing. That said, principal investigators (PIs) have remarkable autonomy in how they organize and run their laboratories. Dr. Huising commented that "Decision making is highly decentralized, and often operates according to verbal agreements. Trust is a very important component in how things get done in these laboratories." Because the laboratories work on soft money, they are often in flux, with continuously changing resources, members, and activities. She also noted that these different professional bureaucracies have implications for biosafety and biosecurity, in particular by determining responsibility for legal and administrative requirements, allocating, authority to enforce those requirements, and facilitating compliance.

Dr. Huising presented key findings from studies of safety culture in biology laboratories. She emphasized that these studies came from BSL2 facilities because of the difficulties in obtaining sustained access to higher containment (BSL3, BSL4) facilities. The findings include:

- Researchers experience compliance requests as intrusions and impediments to their work. They communicate safety as peripheral to their research work and sometimes delegate it to students. They are most likely to incorporate safety features into their practices when they align with efforts to control physical materials.
- Most violations are minor (housekeeping). A small number of laboratories account for the majority of violations.
- Organizations depend on environmental, health, and safety (EHS) staff (such as Biosafety Officers) to ensure compliance.

With regard to the last finding, she noted that the roles of the EHS staff included buffering researchers from record-keeping, inspections, corrections, and helping to maintain compliance. They negotiate increased

daily compliance by working in laboratories, generating familiarity, trust, and relationships, which also gave them the ability to anticipate problems and to identify emerging dangers. In many cases, the EHS staff was able to draw on requirements and regulations to increase their resources and authority in relation to faculty, but she commented that these "boots on the ground" were chronically underfunded.

She noted the emergence of a "responsibility movement" in other facets of the life sciences, with examples of good practice in green chemistry, nanotechnology, synthetic biology, and the citizen science movement. Dr. Huising concluded by providing a number of specific recommendations for developing policy options for GOF research (see Box 2-5).

Gavin Huntley-Fenner from Huntley-Fenner Advisors introduced concepts in human factor research relevant to the NSABB WG's Draft Working Paper and recommendations. Dr. Huntley-Fenner highlighted that, in general, human error has increased proportionally as a contributor to accidents. He recalled that for laboratory biosafety, despite advances in technology, instruments, and personal protective equipment, the World Health Organization had asserted that "human error remains one of the most important factors at the origin of accidents" (WHO, 2006). He noted that there was a lack of data on human reliability in laboratories, and he stressed the importance of collecting more data on safety. He cited the conclusion in the RBA that "The state of knowledge of the rates and consequences of human errors in life science laboratories is too poor to develop robust predictions of the absolute frequency with which laboratory accidents will lead to laboratory acquired infections" (Gryphon Scientific, 2015: 3) to underscore the relevance for GOF policy deliberations.

BOX 2-5
Shaping Cultural Change Relevant to the Oversight of Gain-of-Function Research of Concern

- Culture change should come from within the scientific professions, making it more likely to produce long-term, global changes.
- Particular focus should be placed on the roles of Biosafety Officers in relevant laboratories, and that will require resources and support.
- Research about daily decisions and practices in laboratories needs to be supported and expanded to encompass higher containment facilities, providing for better baseline data.

SOURCE: Huising, 2016.

There are a range of factors that can contribute to the emergence of error, including how physical and cognitive stresses undermine human reliability, according to Dr. Huntley-Fenner. He suggested that the comparative scarcity of accidents might still mask latent risks, with more numerous incidents and errors going unreported. He highlighted research by the Government Accountability Office in 2009 that concluded latent risks still exist in laboratories from underappreciated human error (GAO, 2009). He suggested that human factors research could provide tools for designing, implementing and maintaining systems in which errors are mitigated when they occur. The benefits of incorporating human factor principles were potentially significant, with Dr. Huntley-Fenner suggesting that they could reduce risk associated with GOF studies of concern substantially. He noted that some simple approaches could yield a significant reduction of errors, such as the development and use of simple checklists, which had a significant impact in reducing surgical errors in hospitals in both developed and resource poor countries (Haynes et al., 2009).

Progress has been made in other areas to address shortcomings in human factor safety data. For example, Dr. Huntley-Fenner discussed how the National Aeronautics and Space Administration has succeeded in mining data it already had in ways that provided insights into areas where it had less data, which was then used successfully to reduce risk (Chandler et al., 2010). He argued that limited relevant laboratory safety data do exist. For example, a survey of laboratory acquired infections in 68 institutions in Belgium indicated that 95 percent of the incidents involved human error (Willemarck et al., 2012: 14). He suggested that the human factors research community was well positioned to provide relevant data but more work was needed in high-containment laboratories.

Measuring incidents was only one necessary step; controlling incidents was also important, noted Dr. Huntley-Fenner. He highlighted research that showed the success of applying multifaceted controls. He also highlighted the importance of considering context. Guidance from the United Kingdom on human factors that result in noncompliance with standard operating procedures demonstrated that cutting corners was mainly "due to situational and organizational factors. These factors include, for example, time pressure, workload, staffing levels, training, supervision, and availability of resources" (Bates and Holroyd, 2012). Dr. Huntley-Fenner recommended rigorous data collection and sophisticated analytics to reduce risk associated with GOF studies of concern (see Box 2-6). The self-driving Google car was provided as an example of successfully gathering and leveraging data on human decision making and error to build a system that reduces those risks.

Monica Schoch-Spana from the UPMC Center for Health Security outlined four basic considerations for the design of public deliberations.

BOX 2-6
Improving Rigorous Data Collection and Sophisticated Analytics to Reduce Risk Associated with Gain-of-Function Research of Concern

- Create national reporting standards that go beyond the most significant adverse events
- Collect data on near misses
- Collect data across multiple bodies to counteract relative rarity of events
- Standardize data inputs whenever possible
- Develop analytics driven models of when and what adverse events are more likely to occur and under what circumstances
- Direct training and other interventions where they are needed most

SOURCE: Huntley-Fenner, 2016.

1. **Which public(s) to involve in deliberations**—In the context of GOF studies of concern, Dr. Schoch-Spana suggested that considering three overlapping categories would be useful: the *pure public*, or naive citizens; the *affected public*, or persons or groups whose lives are altered or influenced by a policy decision; and the *partisan public*, or representatives of groups with vested interests or expertise in the policy matter. She also noted that each of these categories of the public had been engaged in past discussions on GOF studies of concern, with the affected public implied in the RBA, affected publics and the pure public noted in the ethics analysis, and partisan publics reflected in relevant publications and comments.
2. **What is the purpose for public(s) deliberation**—Three distinct aims were highlighted: *knowledge exchange*, conveying information from policy makers to publics, or transmitting views, opinions, or attitudes from the publics to policy makers; *innovation*, eliciting rich unpredictable insights that come from crowd-sourcing a problem or from experiential, on-the-ground knowledge; and *democratic accountability*, ensuring broad representation in a decision about the common good. If the public deliberation on GOF studies of concern was intended for democratic accountability, Dr. Schoch-Spana noted it was necessary to give people the time, information, space, and authority they need to perform that role. Merely bringing "ordinary people" or a cross-section of society together to deliberate does not automatically achieve this aim.

She suggested a series of desirable characteristics for public deliberations on GOF studies of concern, including diversity, balance, civility, accountability, and consent.

3. **Which process enables the public to fulfill its purpose**—The use of three types of processes in the GOF deliberative process were reviewed: *communication*, a form of transparency through putting out information for the public—for example, press releases, educational websites, and summary reports such as those made available by the first Academies GOF symposium and the NSABB GOF meetings, as well as making the RBA available online; *consultation*, a means of gathering input, such as through enabling public comments on draft NSABB recommendations and to the U.S. government on future funding and oversight policy; and *collaboration*, a more deliberative option to exchange ideas and share responsibility for making and implementing policy. To date, she felt that the life sciences and other partisan publics have had strong input but deliberation with the broad public has not yet been explored.
4. **On what problem will the public(s) deliberate**—Dr. Schoch-Spana reviewed good practices in identifying problems, especially where there are conflicting values as to the public good, and for controversial and divisive topics. She used them to identify three questions on which the publics might deliberate for GOF studies of concern: (i) Despite potential contributions to public health, should studies that could produce a pathogen of pandemic potential be performed at all?; (ii) Are finite dollars better spent on experiments to create pathogens with pandemic potential (which produce unique knowledge) or on strengthening the rest of the flu preparedness portfolio?; and (iii) If any, what added steps should trustee institutions (e.g., the U.S. government or research entities) take to strengthen pathogen of pandemic potential biosafety and biosecurity protections and public confidence in them?

Dr. Schoch-Spana also discussed how to operationalize standard elements of deliberation design. She noted that there is no single methodology for public deliberation, but she did describe a number of minimum standards for public deliberation, in particular for inclusivity and diversity, the provision of information, value-based reasoning. She also discussed methods for measuring the success of the process. Dr. Schoch-Spana concluded that meetings to date have engaged individuals from the life sciences, security, public health, biosafety, risk analysis, and the drug and vaccine industries, but the general public had been largely absent. She identified an unresolved issue of whether more sophisticated, resource-intensive deliberative sessions could be held outside the present circle

of vested parties. A number of possible activities for such a process were suggested (see Box 2-7).

In opening the floor for discussion, Baruch Fischhoff commented that the panelists had been encouraged to offer recommendations based on their own professional experience and research. He added that for those in the audience who were not familiar with the social, behavioral, and decision sciences, the panel should have provided some idea of the breadth and depth of the research that is available if one wanted to put the human aspect of this enterprise on a scientific foundation. It also illustrated the mix of methods used in this research: various theories; multiple methods of observation, including direct observation and laboratory and field experiments; traditional and statistical and analysis; and various types of data.

Discussion

The resulting discussion further elucidated specific aspects of the presentations. The importance of additional data gathering on accidents and associated human factors research was a repeated theme. Susan Wolf, an NSABB member from the University of Minnesota speaking in her personal capacity, raised operational issues around data collection, data standards, and the development of data collection systems. Gavin Huntley-Fenner commented that the dearth of current data on accidents and human reliability in laboratories does not mean that what people want to know is unknowable. He and others also noted the value as well as the potential challenges in implementing confidential accident reporting. The need to ensure that comprehensive reporting systems for

BOX 2-7
Examples of More Sophisticated, Resource-Intensive Deliberative Activities to Extend the Current Process

- Initiate a formal evaluation process to determine how the (primarily) partisan publics rate the quality of deliberations in terms of inclusivity, information provision, and value-based reasoning.
- Hold deliberative exercises in communities now hosting facilities where GOF studies of concern are undertaken.
- Engage a cross-section of the American public in a deliberative exercise about a specific question.

SOURCE: Schoch-Spana, 2016.

human errors are developed and implemented in a nonpunitive manner was stressed by Kavita Berger from Gryphon Scientific. In response, Dr. Huntley-Fenner noted the importance of even seemingly small things, such as finding language for reporting forms that did not use negative categories ("theft," "loss"), and designing systems so that there was feedback or other incentives for reporting, such as providing information that could be used to improve safety. Ruthanne Huising said that the new regulatory framework developed in Canada had a nonpunitive reporting system that offered potential lessons about dealing with privacy issues and offering useful feedback.

Given what he saw as the difficulties of implementing a nonpunitive system in high-containment laboratories, Andrew Kilianski, a National Research Council Fellow from the Edgewood Chemical Biological Center Aberdeen Proving Ground, made the specific suggestion to conduct research focused on the possible relationships between human error by graduate students under minimal-containment standards and other indicators of their proficiency. Megan Palmer from Stanford University highlighted the importance of strategic interventions to allow sustained scholarship on the social and behavioral dimensions of research. Monica Schoch-Spana commented that best practices for biosafety and biosecurity have not been captured, synthesized, and disseminated by researchers.

Adam Finkel said he was concerned that there had not been a discussion of a confidential channel for reporting incidents, citing what he thought was becoming a less favorable climate for "whistle-blowers" in many settings. He also stressed the need to consider outside incentives to support a culture, including enforcement. He thought that traditional regulation was probably not appropriate but cited other models, such as third-party audits, that could be considered.

Issues around the enforcement of safety and security regimes were also addressed, with some participants noting that a subsection of accidents and incidents are a result of negligence and malfeasance, requiring some form of censure. These individuals highlighted the importance of access to necessary resources for enforcement.

Opportunities for strengthening safety by designing out the consequences for human error were also noted: for example, by Dr. Finkel. He cited useful precedents from health care settings and commented that he sensed opportunities were not being widely studied or implemented in laboratory settings. In response, Dr. Huntley-Fenner noted a paradox that, as one designs out the other sources of error, human factors become an increasing portion of whatever error remains. That is not a reason to neglect those helpful improvements, but it is a reminder that human error will always be with us.

Kavita Berger noted past work on behavioral threat assessments and asked whether there were methods that could be applied earlier to detect individuals who posed potential biosecurity threats such as, for example, someone stealing an agent or animals, vandalism, violence, or deliberate misuse.

Participants discussed a multilayered approach as raised by Dr. Schoch-Spana, highlighting the need to ensure that such a system includes public engagement and transparency at all levels. Susan Wolf asked about the potential value of having a formal FACA committee for GOF studies of concern. Dr. Schoch-Spana commented that a FACA committee would satisfy one level of engagement and could be beneficial, but one should think of shared governance across all levels. She cited the systems in place at Duke University and St. Jude Children's Research Hospital (see next chapter) as examples worth studying for approaches to providing a diversity of views and participants. She commented on the need for more efforts to collect and share best practices about ways to improve biosafety, biosecurity, and what she called "bio-credibility." The potential additional burden imposed on scientists involved with GOF studies of concern from participating in further public deliberation exercises was raised by Margaret Kosal from the Georgia Institute of Technology. She asked if this was another unfunded mandate to educate a sometimes ignorant public that might be hostile to science for reasons that have not come up in these discussions.

David Drew from the Woodrow Wilson Center introduced himself as a "concerned citizen" who had not been familiar with the GOF controversy before the symposium. He raised the issue of whether the type of public engagement by scientists represented at the symposium was actually a form of "upstream engagement," which can be interpreted as designed to defuse the public's concerns without really addressing them. Dr. Schoch-Spana responded that to be effective the public deliberation process needs to be a shared dialogue that leads to mutually agreeable common ground, not just pure persuasion. Silja Vöneky from the University of Freiburg said she appreciated the stress on the value of ensuring that culture change comes from within scientific disciplines. But she also noted other strong incentives for scientists, such as publication, and suggested broader consideration of opportunities to nudge scientists to strengthen their focus on the safety and security implications of their work. Dr. Huising commented that the issue of culture change is sensitive when one is dealing with elites. In this case one was dealing with highly educated elites who are used to substantial autonomy and are not necessarily very open to ideas that are coming from elsewhere. She believed strongly that the ideas about the importance of safety and security in science are going to have to come from some of the best researchers in each

discipline. "We need the leaders in these disciplines to model the importance of these values and normative expectations in research. We need the journals to expect it and conferences to highlight it. It will have to be pushed from within to be effective."

3

Issues for U.S. Policy

THE POLICY LANDSCAPE IN THE UNITED STATES

Michelle Mello from Stanford University, a member of the Symposium Planning Committee, introduced the theme of the session. Key Findings 2 and 3 of the National Science Advisory Board for Biosecurity (NSABB) Working Paper (NSABB, 2015a: 3-4) addressed the adequacy of the policy frameworks in the United States to provide oversight of gain-of-function (GOF) studies of concern. Finding 2 indicates that the frameworks are effective overall, yet Finding 3 suggests that their adequacy for managing the risks associated with GOF research may vary, depending on which pathogen is being studied.

She commented that there seemed to be plenty to discuss about where the policy frameworks may and may not be adequate or optimal for addressing these risks. To that end, the speakers were asked to reflect, depending on their institutions, on the issues facing federal agencies in administering this regulatory framework as well as some of the strengths and weaknesses in the current policy framework and opportunities for optimizing oversight of this area of research.

Gerald Epstein from the Department of Homeland Security reviewed the scope of the NSABB proposal in terms of who is covered, which pathogens and activities are covered, and what is required. In terms of the existing policy context, he wanted to differentiate between those that are in effect by force of law, and therefore affect all researchers in the United States, as opposed to those that are, for example, a condition of government funding, which would directly affect only the recipients of that

funding. There may be indirect effects in other areas, but a funding hook would only directly affect recipients of U.S. government funding.

The first part of the existing regulatory context that affects everyone in the United States is the laws in place to prohibit biological weapons development.[1] This statute is the mechanism by which the United States implements the Biological and Toxin Weapons Convention, an international treaty which prohibits development or acquisition of biological weapons. Unfortunately, the law does not contain definitions of prohibited types of activity or agents, so he thought the level of subjective judgment involved in proving a violation makes prosecution difficult.

Partly for that reason, the Select Agent Regulations were developed and expanded through a series of statutes.[2] This is a comprehensive set of safety and security requirements governing any use of certain listed pathogens. Of the GOF pathogens, three of them—1918 flu, highly pathogenic avian influenza, and severe acute respiratory syndrome (SARS)—fall under these regulations. The Middle East respiratory syndrome (MERS) does not.

Under the Select Agent Regulations, institutions have to be registered, researchers and staff have to be vetted by the government, and the institution has to have permission to use those agents. There are requirements for safety and security and for incident response and reporting associated with use of these pathogens. And in this case, the government does not have to prove intent. If one is found with one of these agents and has not registered with the government, it is a violation of a law. When that law was passed, it was also recognized that there are legitimate and important reasons why these agents need to be used in research. This is why there is a process by which research institutions and people can become vetted and approved to work with these agents. But it does provide a barrier for people who are not within that scheme.

A third area of legislation that binds everyone in the United States is export controls. These affect the export of certain listed pathogens from the United States or the communication of certain nonpublic, proprietary information that could, for example, include information about how to develop a particular strain of a pathogen if that were not published in the open literature. Information that is published in the course of fundamen-

[1] The primary statute to implement U.S. obligations under the Biological and Toxin Weapons Convention is the Biological Weapons Anti-Terrorism Act of 1989 (Public Law 101-298, May 22, 1990).

[2] The Select Agent program was created by the Antiterrorism and Effective Death Penalty Act of 1996 (Public Law 104-132, April 24, 1996). Following the attacks of September 11, 2001, and anthrax mailings, the program was expanded by the USA PATRIOT Act of 2001 (Public Law 107-56, October 26, 2001) and the Public Health Security and Bioterrorism Preparedness and Response Act, known as the Bioterrorism Act of 2002 (Public Law 107-188, June 12, 2002).

tal research is not affected by export controls, but there is a set of statutes and regulations that could have some bearing on the ability to do and disseminate biological research.

Because they had already been discussed, Dr. Epstein touched only on the policies that are attached to government funding. This includes the federal and institutional policies for oversight of dual use research of concern (DURC), which among the GOF pathogens covers only 1918 flu and H5N1 highly pathogenic avian influenza (White House, 2012, 2015b).

He commented that another framework developed by the Department of Health and Human Services (HHS) for certain H5N1 and H7N9 strains was very similar to the structure of the NSABB's recommendations (HHS, 2013). Lawrence Kerr would describe the framework during his presentation.

Dr. Epstein cited *Biosafety in Microbiological and Biomedical Laboratories* (CDC and NIH, 2007) and *Guidelines for Research Involving Recombinant or Synthetic Nucleic Acid Molecules* (NIH, 2013), extensive biosafety and biosecurity guidance that the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) developed for use by anyone doing biological research. It is obligatory as a condition of NIH funding for institutions to follow these processes. This set of best practices enables research using potentially dangerous pathogens to be done safely both for those working in the laboratory and for those in the community. Beyond the formal requirements, this guidance is used widely around the United States, not only for government-funded work, and indeed around the world. Even a policy that nominally has only the force of its ties to government funding can have much greater influence.

Finally, with the caveat that he was not a lawyer, Dr. Epstein cited the issues of the liability that any institution working with potentially hazardous substances could face. Any entity working on something that could pose a risk to its workers, to the neighborhood, or to the environment has to do so in recognition that if there were an accident that causes damage in the community they could be held financially liable. This includes not only harm to the institutions or employees but also harm to the general public. And the extent to which an institution could be held liable may depend on the degree to which there is a regulatory structure in place and whether the institution had been complying with those regulations.

Dr. Epstein commented that any additional development of policy related to GOF research would have to be embedded in the already existing frameworks, and the question of whether these existing procedures would have to be modified to fit the new one or whether they would sit on top would have to be determined as the policy process went ahead.

Dr. Kerr from HHS provided an overview of HHS framework for research with certain highly pathogenic avian influenza viruses (HHS,

2012). Dr. Kerr noted that during the research life cycle, there are points at which biosecurity concerns could be addressed, but it is too difficult—and too damaging to the research enterprise—to do this at the publication stage. Therefore, HHS focused on the research proposal stage as part of the funding award process. He noted that within the existing HHS GOF policy, the focus is on studies that could produce an agent with increased pathogenicity or transmissibility via respiratory droplets. In such cases, an extra level of review is required. The results of the review determine whether a proposal goes on to departmental level review. Seven criteria are taken into account during these reviews (see Box 3-1).

The department-level review provides multidisciplinary expertise—including public health, scientific, security, intelligence, countermeasures, and preparedness and response—from a number of agencies to evaluate these proposals. The department-level review will also identify any additional risk mitigation measures that should be required, and it will determine whether a given proposal is acceptable for HHS funding. For proposals that are deemed acceptable, the funding agency within HHS will make the final funding decision. Dr. Kerr indicated that only a small number of research proposals had undergone a departmental review, but he commented that the results reflected the full spectrum of what one might expect from a review process if it is working well. Some proposals received full approval by the committee and were recommended for funding to the funding agency director. There were also research proposals

BOX 3-1
Criteria Used to Determine If Research Is Relevant to the HHS Framework for Certain H5N1 and H7N9 Influenza GOF Studies

1. Such a virus could be produced through a natural evolutionary process;
2. The research addresses a scientific question with high significance to public health;
3. There are no feasible alternative methods to address the same scientific question in a manner that poses less risk than does the proposed approach;
4. Biosafety risks to laboratory workers and the public can be sufficiently mitigated and managed;
5. Biosecurity risks can be sufficiently mitigated and managed;
6. The research information is anticipated to be broadly shared in order to realize its potential benefits to global health; and
7. The research will be supported through funding mechanisms that facilitate appropriate oversight of the conduct and communication of the research.

SOURCE: Kerr, 2016.

that were received in which individual experiments were rejected by the committee and it was recommended to the funding agency that those not be funded.

Richard Frothingham from Duke University provided an overview of the review process for dual use research instigated by their Institutional Biosafety Committee (IBC), which has been reviewing research for dual-use potential since 2003. Its experiences were recounted in an article in *Science* in 2007 (Davidson et al., 2007). The committee determined that most projects with significant dual use potential were GOF studies, and as a result, it added seven questions to its recombinant DNA registration form in 2005. It also undertook specific training for IBC members on dual use research. The IBC has examined all research including recombinant DNA, select agents, and all research under BSL3 conditions as well as other research upon request.

The Duke IBC does not use a specific dual use definition or threshold but has identified relevant research through the NIH study section or program officer, by the principal investigator's (PI's) answers on the recombinant DNA registration form, or by members of the IBC during the course of its research reviews. Specific examples of GOF identified by the Duke IBC were provided, including cytokine expression by Ectromelia; virulence factors in uropathogenic *E. coli*; adaptation of dengue virus for growth in *Drosophila* cell lines; and HIV infectious molecular clone pseudotyped with vesicular stomatitis virus-G (VSV-G) for initial entry into renal cells. The Duke IBC had learned a number of lessons from having reviewed this research, including:

1. GOF studies were encountered regularly as part of the broad category of dual use research, but the IBC had yet to encounter GOF studies of concern.
2. PIs have had challenges with the concept of dual use research; it was possible to reach consensus on the dual use potential of most biomedical research, but not on specific categories (e.g., DURC).
3. Focusing on specific risk mitigation strategies rather than whether a particular experiment was DURC did enable the IBC to reach consensus, and no GOF research proposals have been rejected.
4. The Duke IBC had received external expert advice on some studies as part of the review process and this had been helpful.

Dr. Frothingham noted that the comparative scarcity of events involving the misuse of research to cause harm makes it difficult to measure the benefits from dual use reviews. He did highlight their value in building public trust in responsible science. He suggested that the early review of GOF research might reduce wasted effort by scientists and improve peer

review and funding outcomes. He concluded by providing a number of perspectives on the NSABB recommendations (see Box 3-2).

Philip Potter from St. Jude Children's Research Hospital introduced the hospital's work on influenza, including its status as one of the National Institute of Allergy and Infectious Diseases' Centers of Excellence for Influenza Research and Surveillance and a World Health Organization Collaborating Center for Studies on the Ecology of Influenza in Animals. Dr. Potter noted that, as a result of their work with influenza viruses, St. Jude is likely to be affected by decisions over the oversight of GOF studies of concern. He highlighted the existence of a specific DURC committee that consists of both scientists and nonscientists. In their system, the PI is responsible for presenting the risks and benefits of the proposed studies. To assist the committee, St. Jude has developed internal guidance on what they should consider. This included ensuring that no GOF virus is resistant to antiviral agents, that suitable vaccines are available, and that advice about the challenges of evaluating risks and benefits in "gray" areas, such as research altering host range and or tropism, is available. The committee has also embraced the ferret as the gold standard for biological testing, requiring its use in all relevant experiments.

The DURC committee has also subjected all experiments involving H7N9 influenza virus to the same scrutiny as the 15 agents covered by DURC requirements. Dr. Potter noted that the DURC committee does

BOX 3-2
Perspectives on the NSABB Recommendations Drawn from the Experiences of the Duke Institutional Biosafety Committee

- GOF is easier to understand than dual use.
- The proposed definition of GOF studies of concern is much clearer than the current DURC definition. It should be possible to reach consensus in determining when GOF research is a GOF study of concern.
- The GOF studies of concern world should be small and definable. There will be substantial overlap with Select Agent programs. Institutional experience with Select Agents will be valuable in implementing GOF review.
- The current IBC or Institutional Review Entity (IRE) mechanisms seem appropriate for institutional GOF review. Institutions should have a low threshold for requesting external expert advice.
- Duke recently moved dual use review, including GOF review, out of the public IBC space to a confidential IRE. The process of GOF review should be transparent but the content is often inappropriate for public disclosure.

SOURCE: Frothingham, 2016.

not publish minutes. He also provided a number of perspectives on the NSABB draft recommendations and broader policy frameworks (see Box 3-3).

Discussion

The discussion that followed addressed local adaptation of the research covered in assessment of DURC or GOF studies of concern. J. Patrick Fitch from the Battelle National Biodefense Institute, a member of the NSABB, speaking in his personal capacity, raised the question of who would be responsible if something went wrong—the scientist or the committee? He also commented that his institutional committee had an experience similar to Duke's. In that situation, a focus on developing appropriate risk mitigation plans for relevant research, rather than on identifying a specific experiment as "DURC," had proved to be a much more productive approach to achieving the same goal.

Following a suggestion by planning committee member Barry Bloom from Harvard University, speaking in his personal capacity, participants also explored whether there was a need for separate IBCs, DURC committees, and possibly GOF studies of concern committees. Some participants felt that it might be possible to combine committees, especially if there was access to the additional expertise that might be required for new roles. Allison Mistry from Gryphon Scientific also proposed updating the DURC requirements to reflect GOF studies of concern and to

BOX 3-3
Perspectives on the NSABB Draft Recommendations and Broader Policy Frameworks

- This is a good initial draft that provides guidance to PIs and Institutional officials.
- The criteria for assessing GOF research are reasonable, but are not specific (terms "highly," "significant," and "likely" should be better defined).
- DURC Committees would likely have the expertise to assess GOF research.
- It is unclear whether local IBC and DURC committees can add additional science as DURC or GOF—if so, this might this lead to a patchwork of institution-dependent rules.
- GOF guidelines need to be crystal clear.
- Need to be specific about who to contact if issues arises.
- If the PI can justify risk/benefit to DURC/IBC committees and the U.S. government, should any GOF studies be prohibited?

SOURCE: Potter, 2016.

avoid creating a separate definition and policy oversight process for GOF research. Christopher Park from the Department of State stressed the importance of the scope of GOF studies of concern in covering both biosafety and biosecurity issues, which set it apart from the DURC process. Richard Frothingham expressed a concern that the DURC institutional process was considerably more cumbersome than the normal IBC process, and he would be reluctant to see them combined.

Dr. Frothingham highlighted the importance of the independence of review committees and their ability to access external expertise. He and Philip Potter discussed the advantages, for example, of including local public health officials in the membership of the IBCs, which both Duke and St. Jude do. Both also have regular contact with the Federal Bureau of Investigation's local Weapons of Mass Destruction coordinator. The importance of clear definitions was stressed by Diane DiEuliis from the National Defense University, while others, such as Mr. Park, highlighted cases where overly detailed definitions undermined the intended aim of the measure. There was a discussion about whether it was better to limit the scope of research likely to be captured under these definitions or, as proposed by Mr. Park, to have a fast-track process for removing research not deemed relevant during the review process. The unique nature of each research proposal was stressed by Dr. DiEuliis, as was the need to consider each proposal in context.

Several participants noted the importance of exploring alternative approaches to GOF studies of concern whenever possible, and the panelists discussed several specific examples of this happening. The value of broader expertise and nonspecialists in identifying alternative research approaches was noted in this regard by Drs. Frothingham and Potter.

Michelle Mello and several of the panelists felt that public trust was an important metric for assessing the efficacy of regimes for DURC and GOF studies of concern. Other participants suggested that reviews of DURC and GOF studies of concern were sensitive and should not be publicly available. Some participants argued that transparency was important and that relevant records should be made available. Both Dr. Frothingham and Gerald Epstein commented on the difficulties posed by the competing goals of protecting potentially sensitive information and ensuring transparency as part of gaining public trust. There were suggestions by Mr. Park, for example, that such information might be made available but not widely distributed.

The discussion also identified a number of tools that might strengthen future efforts. Gregory Koblentz of George Mason University highlighted the importance of learning from past experience. He and other participants called for mechanisms to capture lessons learned in a more systematic fashion. Professor Koblentz also called for additional help for PIs

to understand the underlying concerns that drive assessments of DURC and GOF studies of concern. He also proposed more support to assist regulators in understanding what is possible at the laboratory level and to enable public understanding of the research.

There was also some discussion of the proposal from Silja Vöneky from the University of Freiburg to require laboratories to take out insurance against the risks of GOF studies of concern. Dr. Epstein saw the utility of this proposal—the Department of Homeland Security requires the laboratories it funds for Select Agent research to have insurance. He felt that it would be a useful approach for improving good behavior, although he saw challenges for insurance companies in developing accurate actuarial calculations on these risks.

The definition of GOF studies of concern contained in the NSABB WG's Draft Working Paper was revisited. The third criterion for defining GOF studies of concern was once again the most discussed by some participants, such as planning committee member Dr. Bloom from Harvard University, speaking in his personal capacity, finding no difference between the transmissibility criteria and the one connected to innate or acquired resistance to public health interventions. In connection to the third criterion, Dr. Bloom also raised issues of justice and equity around access to drugs in many parts of the world.

BEST PRACTICES TO INFORM POLICY DESIGN AND IMPLEMENTATION

Philip Dormitzer from the Pfizer Vaccine Research and Development Unit, a member of the Symposium Planning Committee, introduced the session as a continuation of the earlier plenary session on the U.S. policy landscape. This session would present the perspectives of several different key stakeholders, including regulatory agencies and the vaccine industry.

Michael Callahan from the Massachusetts General Hospital and Harvard Medical School opened by highlighting that U.S. efforts to balance the risks and benefits of GOF could be altered for use in other contexts and adapted to the needs of different countries. Dr. Callahan stressed the interconnected nature of the research and development enterprise in the life sciences and for biotechnology, asserting that "the world is flat for bio-innovation." As an example, Dr. Callahan noted that more viral pathogens have been sequenced in China in 4 months than have ever been sequenced in the United States and Europe.

A major theme of Dr. Callahan's remarks was that market-driven and beneficent GOF research is already happening around the world, all of which is outside of the U.S. and European policy and regulatory frameworks. One of his main points was that U.S. and European vaccine

production does not always take cultural and other factors into account. For example, he noted that Western vaccines will only be used in Indonesia if they conform to requirements that make them halal. Another relevant example discussed was the production in Asia of effective and inexpensive H5N1 poultry vaccines. The life span of a chicken in Asia is about 6 months, so Western vaccines costing $7 per dose are not going to be used when Asian-produced vaccines costing pennies per dose are available. He also noted that countries in the group of 112 Non-Aligned Nations may refuse to share pathogen gene sequences with U.S. scientists because "they've been ripped off." He suggested that the U.S. government needs to protect "our international collaborators from R01-funded investigators who seek to do nothing more than get a virus, go home, and write their big *Nature* paper." Dr. Callahan concluded with a series of recommendations for aligning domestic and foreign policies relevant to GOF (see Box 3-4).

Robert Fisher from the Food and Drug Administration (FDA) introduced the FDA's main mission: to ensure that medical products and associated technologies are safe and effective. Dr. Fisher discussed a variety of regulations relevant to the evaluation of products and the implementation of regulatory mechanisms. He highlighted a number of approaches used by the FDA, including randomized clinical trials, surrogate endpoints, and animal efficacy data. He stressed that, regardless of the approach taken, the FDA relies on data for its decision making.

Dr. Fisher noted that the GOF framework focuses on specific agents of concern, or particular pathways of concern, potentially impacting

BOX 3-4
Recommendations for Aligning Domestic and Foreign Policies Relevant to Gain-of-Function Research

- Introducing Institutional Review Boards and Biological Weapons Convention guidance to foreign venture capitalists, incentivizing market entry through compliance.
- Licensing safe, effective, and inexpensive vaccines to foreign markets or exporting rational vaccine designs to foreign providers.
- Ensuring U.S. government–qualified expert review of academic claims for biosafety and pathogen research in foreign research facilities.
- Incentivizing host nation compliance through the use of metrics which demonstrate local benefit.

SOURCE: Callahan, 2016.

FDA-relevant research. However, the narrowing of focus to GOF studies of concern reduces the potential impact considerably. He provided examples of where GOF studies of concern might impact the work of the FDA, including the production of vaccine seeds from molecular clones, or adapting vaccine candidates to grow in cell-based systems rather than egg-based systems. He noted the potential for GOF concerns to impede rapid, large-scale production of vaccines to meet seasonal and emergency needs.

Lessons from the FDA's regulatory experience were also provided: for example, the importance of early and sustained engagement with stakeholders. Dr. Fisher stressed the value of ensuring sufficient flexibility in regulatory regimes and for their implementation.

Jonathan Moreno from the University of Pennsylvania framed his comments as both a bioethicist and a patient—or a "consumer" of the public health benefits of GOF research. Dr. Moreno identified a number of questions that he thought needed to be addressed when considering policy options for dealing with GOF research, including the impact of terminology and the response to the term GOF; the implications of mutants—both natural mutations and escape mutants; the potential for a generalized GOF policy being too broad to implement effectively; the adequacy of safety records for quantifying the risks of laboratory accidents; current levels of accident reporting; the need to address basic research and vaccine development activities where more acceptable or safer alternatives do not exist; determining the realities of the relationship between GOF methods and vaccine development; and the role of basic science during a health emergency.

Dr. Moreno identified five areas where he thought there was consensus relating to the controversy over research and the policy options to address it:

- Much regulation fails to hit the mark for this field and could needlessly delay vaccine development
- Some regulation is needed, for both biosafety and biosecurity
- Biocontainment does not have a perfect record
- Risk mitigation often only requires some imagination
- Sometimes there are acceptable alternatives to GOF studies of concern, even if they are not the best option

He also thought there might be agreement that GOF data alone cannot predict emergence of a pandemic (genotypes to phenotypes), but perhaps this is getting better; the long-term potential of pre-pandemic strain selection could be "transformative" in new vaccine development; humans are vulnerable to certain natural strains that could be targeted for research,

such as bat SARS-like coronavirus strains; and animal model development for SARS and MERS should be permitted.

He highlighted opportunities for public deliberation as to whether all three of the characteristics for GOF studies of concern, as proposed by the NSABB, are needed for an experiment to warrant additional oversight, or whether the production of a pathogen anticipated to possess two of the characteristics would be sufficient. Dr. Moreno highlighted the need to build on best practices when developing capacities to review GOF studies of concern. He reviewed the composition and mission of the Wisconsin Bioterrorism Task Force and the Stanford University benchside ethics consultations as examples to be considered. Dr. Moreno presented a potential model for institutional bodies for the operational review of GOF studies of concern: Risk–Benefit Assessment Teams, or R-BATs (see Box 3-5).

Ethan Settembre from Seqirus provided an overview of the global influenza system that addresses variability in influenza viruses to develop and deliver candidate vaccine viruses. Dr. Settembre described an example of how the system works in practice, detailing vaccine generation over a 4-5 month period in response to the H1N1 influenza pandemic in 2009. He noted that while vaccines can be produced increasingly quickly, pandemics

BOX 3-5
A Proposal for Risk–Benefit Assessment Teams (R-BATs)

Risk–Benefit Assessment Teams should work in an informative and consultative (but not dispositive) manner. The team should encourage researchers to demonstrate that they have considered the risks and benefits at the current stage of their work. These teams are intended to move beyond a paper mechanism to a dynamic, real-time process. In particular, they should

- Be independent and multi-disciplinary.
- Represent the perspectives of both science and security communities.
- Work through an iterative process that spans the life cycle of the research.
- Use a schedule based on milestones and perhaps be able to make unannounced audits.
- Make assessments based on case-specific risk–benefit parameters.
- Help to develop and disseminate best practices for research with GOF studies of concern.

Further consideration would be necessary to determine whether their existence should be voluntary or mandatory.

SOURCE: Moreno, 2016.

emerge even more rapidly, necessitating further research and development. Dr. Settembre highlighted a need to further speed up production of vaccines in response to both pandemic and seasonal influenza events. He discussed a synthetic process for generating vaccine candidates using attenuated backbones and available hemagglutinin and neuraminidase sequences that was developed with the J. Craig Venter Institute and Synthetic Genomics Vaccines, Inc.. The process allows the generation of synthetic influenza viruses that are attenuated, but would allow for speed, accuracy, and high yield. He noted that this is one of the ways to make vaccine viruses to address immediate important medical needs in a short period of time to get ahead of the wave of infection. This approach had been used to produce an H7N9 vaccine candidate in 2013.

Discussion

The discussion that followed included both an interchange among the panellists and questions and comments from the audience. Among other topics, the discussion returned to considering different ways of defining GOF studies of concern. Philip Dormitzer pointed out that not all GOF research involves GOF studies of concern, and therefore not all the research needs to be overseen by any additional policy frameworks. Following his comments, panelists and participants discussed the subjective nature of determining what is (and what is not) of concern. Michael Callahan argued that any definition for GOF studies of concern needs to be general, adaptive, and culturally appropriate for foreign scientific communities. Participants noted that specialist terminology might not translate well into other languages and settings: for example, Dr. Callahan noted long-standing issues around the meaning of "biosecurity."

Participants also reexamined the importance of ensuring that the process to consider policy options, as well as any new frameworks it produces, cover both the public and the private sector. The importance of adequate containment for GOF studies of concern was another reoccurring theme during the discussions. The issue of enforcement was also revisited. Possible unintended consequences for new policy frameworks to oversee GOF studies of concern were discussed by Dr. Callahan, and possibilities of a negative impact on vaccine production were considered. The risks of regulatory uncertainty were also addressed, with some participants arguing that regulatory burdens are more acceptable when the "what" and the "why" are clear. Issues around the harmonization of domestic oversight regimes, such as those for DURC and GOF studies of concern, were also highlighted by Robert Fisher. Some participants called for the development of a more overarching framework to deal with risks and benefits from life sciences research.

The international implications of determining thresholds of concern or acceptable risk were considered, as well as international perceptions about why the United States might be concerned about this research. Dr. Callahan suggested that it was important to understand the nature and motivation of relevant international stakeholders to improve the dialogue on GOF research. To this end, he noted the importance of strengthening research collaborations, in particular working more closely with partners inside their countries. Gregory Koblentz asked whether it was time to move beyond stovepiped concepts of "biosafety" and "biosecurity" to adopt a more holistic concept of "biorisk management." Dr. Fisher responded that, from a regulator's viewpoint, to the extent that such an approach could reduce uncertainty, it could be helpful.

There was an exploration of the impact of over-regulating GOF research for countermeasure development. Dr. Dormitzer pointed out that, because one of the factors for identifying GOF studies of concern is the absence of effective countermeasures, limiting research that could provide such measures could be counterproductive. There was also consideration of the opportunity costs of not doing research, especially in justifying potential barriers to developing countermeasures. Issues around intellectual property were also explored, with Dr. Callahan discussing barriers for the development of countermeasures, or barriers to the conduct of science internationally. There was a call to change the incentives for countermeasure development—to produce more players, more stakeholders, and therefore more solutions. To this end, Dr. Callahan recommended that greater attention be paid to foreign industry, as an increasing number of products and self-sufficient markets were being developed.

Challenges in disease surveillance were discussed. While some participants suggested that knowledge produced by GOF research could be useful for detecting emerging pathogens, others noted the lack of current surveillance capacity. Current shortcomings in data sharing and capacity for disease surveillance can also distort risks from disease and the impact of public health measures, according to Dr. Callahan. He also noted international concerns that disease surveillance data and capabilities are being used for nonpublic health purposes.

4

International Policy

INTERNATIONAL DIMENSIONS OF GAIN-OF-FUNCTION RESEARCH

Barry Bloom from Harvard University, a member of the Symposium Planning Committee, introduced the session by noting that, as had already become clear in earlier discussions, the issues related to gain-of-function (GOF) research were not confined to the United States. This session would provide background and insights about the international dimensions of GOF research and illustrate the ways in which various organizations outside the United States have been contributing to the discussions from the beginning.

Ruxandra Draghia-Akli from the Health Research Directorate of the European Commission introduced the European Union (EU) innovation framework Horizon 2020. With a budget of €79 billion, the program is intended to support research and development that is increasingly complex, interdisciplinary, and costly, and that also requires a critical mass. It provides a vehicle for increased collaboration across the 28 countries of Europe. The Horizon 2020 framework covers a broad range of research and development activities; most relevant to GOF research is the section on Societal Challenge 1: Health, Demographic Change and Wellbeing, with a budget of €7.4 billion. The research funded under this framework has to have civil or public health applications. Any dual use potential is unintentional.

There has been no specific call for proposals on GOF research according to Dr. Draghia-Akli, but under the health calls, proposals were encour-

aged to strengthen research on prediction, identification, modeling, and surveillance of newly emerging infectious diseases in humans, and to identify factors promoting the emergence of pathogens with human pandemic potential from pathogens with a zoonotic background and related prevention strategies. Both of these areas could potentially result in proposals involving GOF research. Five EU-funded research projects with GOF elements were identified: (i) EMPERIE (European Management Platform for Emerging and Re-emerging Infectious Disease Entities, 2009-2014); (ii) PREDEMICS (Preparedness, Prediction and Prevention of Emerging Zoonotic Viruses with Pandemic Potential using Multidisciplinary Approaches, 2011-2016); (iii) ANTIGONE (Anticipating the Global Onset of Novel Epidemics, 2011-2016); (iv) AntiBotABE (Neutralizing antibodies against botulinum toxins A,B,E, 2010-2015); and (v) TIRAMISU (Humanitarian Demining Toolbox, 2012-2016).

Dr. Draghia-Akli then outlined the ethics review processes that research undergoes in Horizon 2020.

- During proposal preparation, applicants are asked if their proposal has an exclusive civilian focus on research and if their research uses or produces goods or information that will require export licenses in accordance with legislation on dual use items.
- Ethical screening is carried out for each successful proposal by at least two ethics experts, drawing on a variety of different backgrounds, including law, philosophy, medicine, and biology.
- A full ethical assessment for all proposals containing potential dual use issues is carried out by at least five ethical experts.
- At the end of the whole process, the ethics report determines if the project has clearance, requiring no further action; conditional clearance, requiring changes to be made to the description of work (such as requirements for permits, follow-up, or ethical audits); or no clearance, meaning that the project will not be funded.

There has also been specific dialogue with stakeholders in the European Union on GOF research, including the European Society for Virology, which has a common policy for scientific research and publications; the Foundation for Vaccine Research, which has called for a comprehensive risk–benefit assessment of GOF studies of concern; and the European Academies Science Advisory Council (EASAC), which established a working group in autumn 2014 to explore consensus on key questions, identify further GOF issues, and clarify options for policy development. The European Union acknowledged the need to improve awareness and best practices among members of the scientific community and to promote an underlying culture of responsibility, given the potential for

accidental release and misuse. The European Union also welcomed the EASAC working group recommendations (EASAC, 2015a; see the comments by Volker ter Meulen).

Dr. Draghia-Akli provided three different approaches toward implementation within the European Union: researcher-based approaches, as used in the United Kingdom; researchers being overseen by institutions, as used in the Netherlands; and supervision by a national agency, as used in France.

Volker ter Meulen, the chair of the EASAC working group, introduced his institution. EASAC was formed in 2001 to enable European national academies of science to collaborate in giving advice to EU policy makers (e.g., the European Commission and Parliament). Its membership comprises all EU national academies of science plus Norway and Switzerland, and its objective is to deliver consensus outputs to provide a means for the collective voice of European science to be heard. Dr. ter Meulen explained that the EU scientific community had expressed differing views to the president of the European Commission in 2013 on relative benefits and risks of GOF influenza virus (H5N1) research (European Society for Virology, 2013; Foundation for Vaccine Research, 2013). As a result, the European Commission and its chief scientific adviser requested EASAC to clarify and advise on these issues. EASAC brought together scientists, nominated by its member academies, who represented a mix of expertise and a wide range of views about the GOF controversy. The group sought to find areas of consensus as well as issues that had not been resolved. Its report also offered recommendations about what further analysis would be necessary to assess future options for research with potentially pandemic pathogens. The report also identified which of the European Union's current regulations applied to GOF research, how national- and EU-level responsibility should be divided, and what best practices already exist at the national level that could inform other countries.

During the course of this work, EASAC identified a range of critical issues to consider when addressing GOF research as well as key messages, which are summarized in Box 4-1.

EASAC has subsequently produced messages to academies of science worldwide, policy makers in EU institutions, and EU member states as well as to research funding bodies, regulatory bodies, professional societies, and others in the scientific community. It has also worked to catalyze further broad engagement via member academies.

Dr. ter Meulen concluded by providing some insights for strengthening international consideration of GOF issues, including the importance of addressing differences in understanding and in systems between countries and regions; ensuring layered, integrated approaches; building

BOX 4-1
Key Messages from the European Academies Science Advisory Council's Work on Gain-of-Function Research

Self-regulation and harmonization

- Good practice requires conforming with regulations, safety provisions, codes of conduct, and justifying proposed research.
- Self-regulation means instigating a series of checks and balances on research within the scientific community. It requires raising awareness among researchers and their institutions, thereby necessitating education.
- Attention to biosafety issues is needed at all stages of the research life cycle.
- There is a continuing role for Academies of Science in promoting biosafety and biosecurity norms and supporting audits of research practices.

Benefit–risk assessment

- This is not a "once and for all" calculation but a continuing, collective commitment to understand and communicate the issues.
- Incommensurable parameters measured in risk and benefit do not allow a value-free determination to be made.
- Questions remain as to the feasibility of quantifying benefit as prospective public health impact or describing its impact on the generation of scientific knowledge.
- Academies and learned societies need to continue to promote discussion across the scientific community and with other stakeholders.

EU/national activities and organizations in biosafety and biosecurity

- There is a possible role for the European Commission (DG Sante) Health Security Committee in collating available information.
- Guidance is needed for research funded by Horizon 2020 as well as at the national level.
- All researchers and institutions need to conform with EU regulations as implemented nationally.
- No new EU-level body was recommended.
- Member states should have clear national advisory approaches and governance mechanisms with statutory powers.

Publication of sensitive information

- Researchers and their institutions all have responsibility to make decisions about publishing sensitive information.
- Journals should be encouraged to seek appropriate advice, including from security experts.
- Export control regulations are an inappropriate and ineffective vehicle to block publication.
- The European Commission's (DG Research) attempts to raise awareness about revision of these regulations are welcome—researchers should continue to inform policy-makers about these issues.

continued

BOX 4-1 Continued

Public engagement

- Trust and openness are crucial for researchers and their institutions.
- Academies and others in the scientific community should actively participate in public dialogue—articulating objectives for research, the potential for benefit and risk, and biorisk management practices adopted.
- EASAC is committed to continuing working with academies to promote engagement.

SOURCES: EASAC, 2015a,b; ter Meulen, 2016.

links between researchers, policy makers, and other stakeholders; and a continuing commitment to public engagement.

Silja Vöneky from the University of Freiburg discussed the German Ethics Council (GEC) report on biosecurity from 2014 (German Ethics Council, 2014). Dr. Vöneky introduced the GEC, noting that it is an interdisciplinary independent counsel of experts whose 26 members are appointed by the president of the German parliament. She reviewed recent work exploring options for biosecurity for research and health and noted that the GEC report explored biosecurity issues but not biosafety because the regulatory regimes associated with biosafety are much more developed.

Dr. Vöneky presented five recommendations for future GOF research based on the findings of the GEC report (see Box 4-2). These recommendations reflected those proposed for use within Europe, focused on five different areas of governance: raising the level of awareness on biosecurity among the scientific community; elaborating national biosecurity codes of conduct; reviewing research funding; making specific national recommendations tailored to national needs; and developing European and international initiatives.

In the German context, Dr. Vöneky recalled that the GEC had recommended that an appropriate definition of the research of concern should be included in an act of parliament; the definition should be further developed by detailing relevant groups of experiments in a statutory instrument or regulation; and a list of agents associated with the research should be developed. She commented that the list of agents will need to be updated to reflect advances in the life sciences, suggesting that it should not be listed in legislation.

Dr. Vöneky noted that it was difficult to assess the impact of these recommendations over the year since they were made. She highlighted

BOX 4-2
Recommendations for Future GOF Research Based on the Findings of the GEC Report on Biosecurity

Raising awareness in the scientific community—To promote responsible research and improve knowledge of, and access to, relevant resources. One approach to raising awareness was to integrate biosecurity components into undergraduate and graduate life science curriculum.

The use of codes of conduct—Codes were deemed to be practical tools to define responsible approaches for dealing with biosecurity challenges, including by detailing concrete obligations to minimize risk. They were felt to be useful instruments for self-regulation and can be supplemented by broader standards. Codes of conduct could be adapted to address GOF issues, including thresholds for GOF studies of concern.

Strengthening the role of research funding in ensuring responsible conduct—Funding of GOF research should require adoption and adherence to the above code of conduct. Specific funding guidance should be developed ensuring that GOF studies of concern are not funded when there is no need to use GOF approaches or when the risks outweigh the benefits.

Establish a new commission to oversee GOF studies of concern – An independent body, with interdisciplinary membership and participation by civil society, should define GOF studies of concern, conduct risk–benefit analysis of specific research proposals, decide on any additional measures to mitigate or manage risks associated with the research, and undertake relevant consultative roles. It should become a legal obligation to consult the commission before undertaking GOF studies of concern.

Regional and international engagement—Common standards can play an important role in addressing biosafety and biosecurity concerns related to GOF studies of concern. Efforts within scientific communities should continue to develop a common understanding on what constitutes responsible research. An attempt should be made to develop an international code of conduct. At a regional level, States should advocate for a common position on the funding of GOF studies of concern. States should also work internationally to define and classify dual use research of concern (DURC) and GOF studies of concern and appropriate biosafety and biosecurity precautions for undertaking such work. A new international instrument to define the fundamental principles and limitations of GOF studies of concern should be negotiated. This could be a formal treaty or more likely a soft law instrument.

SOURCE: Vöneky, 2016.

progress in Germany in the promulgation of codes of conduct to address DURC issues, and she discussed the implementation of such codes in a number of research institutions.

Dr. Vöneky also highlighted a number of other results that might be relevant to GOF discussions. She believed that soft measures, such as requirements connected to funding, might be less suitable in the EU context. She suggested that measures to evaluate and manage risks associated with GOF research would need to be either codified by states into appropriate laws and regulations or contained with other legal frameworks such as constitutions or international treaties because of competing interests between the rights and freedoms of science and scientists and rights associated with the right to life and health for other parts of the population. Dr. Vöneky noted that the work undertaken by the GEC revealed that existing legal rules governing GOF research in Germany and Europe are insufficient and need to be more coherent. She highlighted internal inconsistencies around the publication of results and funding arrangements.

Dr. Vöneky concluded by stressing the need to balance scientific freedoms and responsible research with the need for proportional measures that do not unnecessarily impede research but do help to manage risks. She reflected on thresholds for GOF studies of concern, suggesting that such a concept might usefully capture experiments that might result in pathogens, which increase the danger of an epidemic of a severe human disease. She felt that such experiments should not be undertaken unless a direct, concrete, and overwhelming benefit for life or human health is probable.

Keiji Fukuda from the World Health Organization (WHO) explained that the world is currently facing a broad mix of issues and uncertainties related to genetic technologies and their potential to do harm, such as GOF research. Other approaches, such as synthetic biology, offer ways to generate novel organisms. Furthermore, Dr. Fukuda noted that the nature of these challenges is evolving as access to the necessary technologies changes: for example, through the emergence of cheaper technology and the advent of private community laboratories. Dr. Fukuda also noted that the entry into force of the Nagoya Protocol on sharing the benefits of biological resources also impacts this space. Furthermore, he recalled that developments, such as the WHO Pandemic Influenza Preparedness Framework deal with not only the movement of viruses but also the movement of sequence information. Dr. Fukuda noted that while these are critical international issues, global awareness of them and how they intersect remains minimal. He highlighted the lack of a clear strategy and outstanding questions as to whether they should they be dealt with separately or were better addressed together. Dr. Fukuda recalled that while

risk assessment can be a scientific and precise process, risk perception, tolerance and management are cultural, political, and, at the global level, consensus based. Dr. Fukuda presented four options for further work on GOF research (see Box 4-3).

Discussion

Barry Bloom led a moderated discussion among the panelists. They explored opportunities for interaction between U.S. and European efforts to address GOF research, with Dr. Draghia-Akli expressing how beneficial such exchanges on common policy problems could be. The importance of information exchange was repeatedly expressed. One panelist felt that the European Union was likely to be flexible about approaches to the biosecurity aspects of GOF research, but noted that given the highly developed arrangements already in place there may be less opportunity to influence biosafety policy. The complexity of the European regulatory architecture was also noted, with one panelist suggesting that additional measures were added but rarely replaced existing arrangements. A trend toward the European Union engaging international partners was highlighted, especially through the development of principle-based voluntary frameworks that could be implemented by partners. Past collaborations between the United States and the European Union were noted on health and biomedical related policy development: for example, bringing together funding agencies to streamline work on rare diseases. Past examples also included collaboration on sensitive issues, such as data and sample sharing.

BOX 4-3
Four Options for Further Work on GOF Research

- Options for going forward will necessitate developing global consensus on technical aspects, such as issues, principles, definitions, and terminology.
- At an operational level, there are examples of programmatic activities implemented by WHO that might offer models, such as the prequalification of laboratories, the oversight of smallpox research and the inspection of the laboratories conducting research.
- Multilateral forums such as the Biological and Toxin Weapons Convention or the International Health Regulations might be suitable venues for addressing specific aspects of GOF but will likely be time consuming.
- Member state funding and support is essential regardless of what approach is taken.

SOURCE: Fukuda, 2016

Panelists also considered options for attempting to ensure that GOF studies of concern were conducted only under appropriate safety conditions. At the suggestion of Barry Bloom, panel members discussed precedents used elsewhere for the prequalification of appropriate laboratories, assessing them against predetermined capabilities: for example, those used for quality control of laboratories used by United Nations agencies. Several participants supported such an approach but highlighted that it would be necessary to consider carefully what the desirable capabilities would be. Other participants felt that the GOF studies of concern context was considerably more complicated than the purposes for which prequalification has been used in the past, and they suggested that the desirable capabilities would be too context dependent for such an approach. They also noted that the number of relevant facilities might be larger than those found in other areas where prequalification has been used.

An open discussion followed and consideration of prequalification of laboratories continued. Gavin Huntley-Fenner questioned which international organization might oversee such an approach. WHO, the International Standards Organization, and the United Nations Educational, Scientific and Cultural Organization were discussed. Keiji Fukuda stressed the importance of any hosting organization being perceived to be neutral and having the trust of key stakeholders.

Issues around standards and harmonized approaches were also explored. Harvey Fineberg, chair of the Symposium Planning Committee, noted that in certain cases—such as for the approval of medicines, drugs, and other medical devices—there was still a notable degree of difference in what is approved, and when, despite a comparatively common agreement on the characteristics to be assessed, relatively straightforward measurements, and well-established decision-making processes. Other participants noted that in the European context, while risk assessment might be carried out collectively, regulatory approval still happened at the national level. Some participants suggested that the chances of creating a common system for GOF studies of concern in the short term were small, especially given the absence of a common definition. Other participants noted that the number of scientists and laboratories potentially conducting GOF studies of concern was currently limited and that there might be opportunities to develop common standards— for example, for biosafety precautions—among the relevant community.

The possibility for developing common approaches between the United States and Europe was also explored, with Silja Vöneky suggesting that reaching such an agreement might help jump-start a broader international process. Michael Callahan felt that a broader buy-in from the start would help legitimize the process. To underscore that argument, Piers Millett from Biosecure transmitted the views on GOF of the 112 states that

comprise the Group of Non-Aligned Movement and Other States under the Biological Weapons Convention (BWC) by reading aloud from the Group's statement to the BWC.[1]

There was also an exploration of whether harmonization efforts should be scientist-led or state-led, with different participants favoring different models. Some participants noted that, at present, GOF studies of concern were largely confined to public institutions, enabling governments to play a leading role. Others noted that only a limited number of states had so far shown an interest in GOF studies of concern, suggesting that a scientist-based, bottom-up approach may help increase government interest around the world. There were also discussions of whether a formal approach was needed, requiring international instruments, or a more informal approach might be more suitable, perhaps through appropriate guidelines such as those used to underpin international efforts on infection prevention and control. Participants also discussed the value of strengthening a culture of responsible research among relevant scientific communities, noting that they had key insights into the risks associated with GOF studies of concern.

The changing distribution of research capacities, sources of funding, and the markets they serve were also discussed. Some participants noted that these developments complicated efforts to address GOF studies of concern, and others noted that it required additional efforts to understand a broader variety of motivations for and contexts within which GOF research might be conducted. Participants discussed incentivizing industry participation, alternative funding strategies and business models in general, and public–private partnerships in particular, for dealing with changes in markets, funding and demographics. Participants provided a number of examples of successful precedents, including the Innovative

[1] The statement is "there have been recent advances demonstrating the increasing sophistication of synthetic biology, together with other enabling technologies, which have benefits, together with the potential for uses contrary to the provisions of the Convention. All states must conduct such activities in a transparent manner, in order to build the confidence of other States Parties. There is a need to regulate these activities, to ensure that they do not lead to any concerns related to ethics, safety and security as well as any uses contrary to the Convention. This has assumed added importance in the light of reports concerning experiments that have been taking place on highly contagious virulent flu strains like H5N1, as well as the production of several new strains of viruses that are both contagious and deadlier than the 1918 Spanish flu that killed almost 50 million people, and the discovery of the deadly smallpox variola virus dating back to the 1950s. Such regulation must, however, be undertaken in a manner that does not hamper scientific and technological developments that are in keeping with the spirit and letter of the Convention, which are of benefit, more especially to developing countries." It is available at http://www.unog.ch/80256EDD006B8954/(httpAssets)/DF2D9E3CAA6D5FEDC1257EA400369E6E/$file/NAM+Statement+on+S&T+MX+2015-3+final.pdf.

Medicine Initiative in the European Union, and global networks for building preparedness for emerging epidemics.

OPPORTUNITIES TO HARMONIZE GOF RESEARCH POLICY AND PRACTICE

Ronald Atlas from the University of Louisville, a member of the Symposium Planning Committee, introduced the session. The plenary on the first day provided participants with an awareness of the international context within which the GOF controversy has evolved. The purpose of this session was to look ahead, to explore the potential for increasing international coordination of policy and practice for GOF studies of concern. What are the opportunities in different regions, including those where the research is performed and those where the pathogens of concern are endemic? What roles might national governments take in fostering efforts at coordination? What are some of the international venues, such as regional or international organizations, where discussions could take place and policy options could be developed? What are the roles for national and international scientific organizations?

George Gao from the Chinese Academy of Sciences and the Chinese Center for Disease Control and Prevention began by discussing risk and benefit. Dr. Gao discussed an example of the H7N9 influenza virus, noting that study of the virus could be directed at finding a mutation in the receptor binding site that might be responsible for allowing the virus to switch from an avian to a human host and allow the virus to transmit to humans. Dr. Gao noted, however, that checking all possible genetic combinations is infeasible, and, given the importance placed on finding the mutations responsible, a GOF approach proved most efficient.

Dr. Gao stressed the importance of international collaboration, cooperation, and harmonization. He recalled one case where two researchers, one in the United States and another in China, were collaborating on research connected to Golden Rice. The contents of the underpinning agreement were different in Chinese and English, which led to misunderstandings and substantial impediments to the research. He felt that harmonization was needed on more than just policy development and that it was necessary to have oversight of the research being undertaken. He suggested that it is important to monitor what is happening in laboratories. Dr. Gao noted the need for a suitable international forum for discussions at the government level. He felt that it was important for top officials in many countries to engage with this issue. He suggested, however, that in many countries there were still opportunities for greater domestic harmonization of relevant rules and regulatory approaches.

The interests of scientists often drive the direction and approaches to research, Dr. Gao noted. Therefore, he felt that it was important to engage with individual researchers on these issues. He believed that GOF experiments should be done in highly regulated laboratories and undertaken only by the best scientists.

Gabriel Leung from The University of Hong Kong began by considering GOF research in context. He noted that this was a discussion of risk to humans and, to a lesser extent, ecological security. He underscored that this was an international issue because pathogens do not respect borders. Dr. Leung suggested this is also a global security issue, not only a U.S. national health security concern. He felt that the primary outcome of policy discussions should be conclusions as how best to keep the global population safe from potential consequences of pathogens that were highly virulent, highly transmissible, and/or resistant to public health interventions.

Hazard analysis, according to Dr. Leung, was a critical control point. He highlighted lessons that might be learned from food safety experiences. Dr. Leung suggested that it was necessary to look for the weakest link in the global supply chain and argued that, in the case of GOF studies of concern, it was a lack of public health preparedness. He recalled that the majority of countries around the world had self-declared their inability to meet core requirements under the International Health Regulations. He suggested that investing in global capacity to respond to disease minimizes the proportion of GOF studies of concern that would then be of concern. To this end he commended the recommendations of the recently released report of an international commission hosted by the National Academy of Medicine on which he had served (Commission on a Global Health Risk Framework for the Future, 2015).

Dr. Leung noted that a highly organized regime for governance of GOF research was important for obtaining human security. He felt that the issue had been largely ignored elsewhere in the world. While he acknowledged that a national policy in the United States would have a global impact, he noted that its relevance should not be overestimated. Stringent arrangements in the United States, or a ban on GOF studies of concern, according to Dr. Leung, would not stop risks to the global population from research carried out in other countries.

Dr. Leung also argued that overly burdensome regulations can lead to unanticipated consequences—perhaps driving GOF research underground or possibly relocating it to other countries without such regulations. He expressed concern over how the broad findings of the National Science Advisory Board for Biosecurity might be translated into guidance and implemented by IBCs in institutions. He felt that greater clarity, especially as to what is (and what would not be) permitted, was needed,

as was more guidance on the implementation of the proposed policy framework.

Dr. Leung provided a number of specific reactions to the inputs to the symposium (see Box 4-4) and concluded that responsible science with robust oversight of GOF studies of concern is warranted, but it should "not squeeze the lifeblood out of scientific enterprise." He felt that the balance between the two must be clearly defined and continually fine-tuned.

Nisreen AL-Hmoud from the Royal Scientific Society of Jordan noted that understanding life processes is becoming ever more important in terms of health, nutrition, and industrial application. Dr. AL-Hmoud suggested that the Middle East and North Africa (MENA) region lags behind other parts of the world in addressing issues in life sciences research.

BOX 4-4
Issues for Further Consideration When Considering Opportunities for International Harmonization of Approaches to GOF Research

- Is there any unique value or value-added from GOF studies of concern or can alternative methods exhaustively derive the same knowledge set?
- GOF research has led to new characterization of pathogens as well as follow-up research identifying new markers of mammalian adaptation.
- Is the proposed third criterion of a GOF study of concern truly orthogonal to the other two dimensions of transmissibility and virulence? Is there an advantage, for example, in better defining or making more encompassing the two truly orthogonal axes of transmissibility and virulence as the product of host-agent interactions as opposed to just innate properties of the agent alone?
- Do we need another layer of regulations or could existing regimes be adapted?
- More consideration may be warranted as to the unintended or intended consequences of policy options. Particular focus should be placed on avoiding such heavy burdens on GOF studies of concern that the research is avoided altogether.
- Financing has always been a powerful modifier of behavior and offers opportunities for shaping engagement on GOF studies of concern.
- Conflicts of interest should be avoided. It is to be hoped that situating the bodies reviewing research for GOF studies of concern inside the same agency that funds the research does not provide a conflict of interest.
- The RBA (risk and benefit assessment) is far from a trivial exercise but more work is necessary to definitively resolve the original questions posed. While it is difficult to draw direct lessons from an RBA exercise, we are now in a better place to understand what we do not know and how much we need to learn.

SOURCE: Leung, 2016.

She stressed the importance for the region of greater progress in ensuring that natural diseases are contained as soon as possible; that harmful consequences of research are minimized; and that laboratories operate safely—both for their workforces and for the communities in which they are situated.

While controversies around research involving highly pathogenic avian influenza virus and the Middle East respiratory syndrome coronavirus (MERS-CoV) have generated considerable discussion and debate among virologists, public health scientists, and experts in the United States and certain other parts of the world, a considerable need for raising awareness about GOF research persists in the MENA. This is needed for laboratory directors and policy makers as well as for life scientists. For maximum benefit, Dr. AL-Hmoud argued that policies and practices aimed at reducing and managing risks should be planned in a holistic manner as part of national safety and security strategies. She noted that, while some countries have begun to develop such plans, many others have not.

Dr. AL-Hmoud noted that while risks vary from region to region, and from one country to another, without a common methodology for assessing risks and for having appropriate policies and practices to manage and mitigate these risks, any international effort will be neither comprehensive nor effective. The countries in the region have explicitly recognized the need for comprehensive scientific strategies, and Dr. AL-Hmoud reviewed efforts under the Biosafety and Biosecurity International Conference series as an example.

Dr. AL-Hmoud stressed the public health impact of coronaviruses, in particular MERS-CoV, and she recalled that the antigenic relationships among the different coronaviruses or how these relationships influence the capacity of different strains to emerge in human populations remains uncharacterized. While she noted progress in relevant tools and information, Dr. AL-Hmoud also stressed that important research questions need to be explored further and they must address potential issues around security and select agent status. She highlighted opportunities for the MENA region to learn from the experiences of other regions, to adopt best practices, and to develop networks of experts.

Dr. AL-Hmoud discussed the importance of developing systematic programs that strengthen human capacity for safe and secure handling, importing, and exporting pathogens to strengthen the oversight of GOF research. She highlighted the need for certain infrastructure and policies at the national level. Dr. AL-Hmoud suggested that these programs should offer considerable regional and international benefits by reducing risks from pandemics and epidemics, regardless of whether they are natural, accidental, or deliberate. To reduce the risk of biological accidents, Dr. AL-Hmoud called for better safety standards and practices,

and improved designs and procedures for security systems at biological facilities. In relation to GOF research, Dr. AL-Hmoud also noted the need for better education and training, more awareness raising, detailed consideration of unintended consequences, and broader adoption of best practices and codes of ethics.

Michael Selgelid from Monash University in Australia suggested that too much of the deliberative process and decision making on GOF research had been restricted to scientists. He argued that there had not been sufficient involvement of the general public and that there was a need for greater engagement of a wider range of stakeholders, including those from other countries.

Dr. Selgelid felt that some policy decisions, especially on risks affecting the global community, could only be made by an international body. He suggested that GOF research poses issues of global justice, including sharing of the benefits of this research. If the risks are universal, there may be issues if the benefits are available only to some of the countries. Dr. Selgelid felt this was particularly important for medical countermeasures. He also noted that a decision to conduct GOF studies of concern in only maximum-containment facilities would effectively preclude the majority of countries from undertaking such work. Dr. Selgelid suggested that WHO was the most legitimate international body to make decisions about GOF research. He discussed the possibility of creating a new WHO committee, similar to the body that oversees smallpox research, to undertake such a task. Dr. Selgelid also discussed the possibility of developing a new stand-alone body for the oversight of GOF studies of concern.

Dr. Selgelid noted that some countries are more likely to be exposed to risk from GOF research than others, especially where vaccines or therapeutics available in richer countries are not available in poorer countries. He noted that differences in access to basic healthcare could also result in an uneven risk distribution from GOF studies of concern.

He highlighted a number of lessons from earlier discussions of DURC. For example, he reviewed findings from the 2010 WHO guidance document *Responsible Life Sciences Research for Global Health Security* (WHO, 2010) (see Box 4-5). Dr. Selgelid also identified a number of approaches for harmonizing GOF research policy. He noted possibilities for gathering greater input from other countries bilaterally. He discussed a collective international harmonization process to create a level playing field. He also considered a more formal international governance regime for policy making and decision making. Dr. Selgelid reviewed the possibilities for using different frameworks, either by strengthening existing treaties or by creating new international agreements or compacts. He cautioned that these more formal arrangements would be difficult to achieve and involve a great deal of work. He also noted more standards-based approaches to

BOX 4-5
Insights for GOF Policy Making Drawn from Past Discussions on Responsible Life Sciences Research for Global Health Security

- There will not be one-size-fits-all approaches to managing risks—some solutions make more sense in some places than others.
- Opportunities to leverage existing regulations and governance structures should be explored whenever possible.
- If additional measures are needed to deal with GOF, expanding existing committees overseeing research might be considered rather than building new ones.
- There are different levels that can be used to address concerns over research: some approaches can be undertaken by individual scientists; other activities can be conducted at the institutional level; professional scientific bodies need to make certain decisions (such as on codes of conduct); other decisions need to be made by domestic governance (such as on regulations or education); and funding bodies can play an important role by taking risks into account when making funding decisions.

SOURCE: Selgelid, 2016.

governance, discussing the framework in place governing human subjects research and suggesting that the ethics governance regime might be expanded to include oversight of GOF studies of concern.

Discussion

The discussion that followed expanded on ideas and concepts introduced during the presentations. Participants explored the comparative advantages of using a standards-based approach based on the existing ethics governance regime. Michael Selgelid again argued this might be easier than a treaty-based approach because it could take advantage of existing policy frameworks and offer logistical benefits. Participants also discussed whether international harmonization might be best achieved through international organizations or international scientific bodies. Some participants felt that both approaches should be pursued in concert. Opportunities for using insurance requirements to harmonize GOF approaches were also discussed, and David Stanley introduced a concrete proposal from the Future of Humanity Institute to utilize the grant making process to address potential risks (Cotton-Barratt et al., 2016). The institute proposed to "price the expected value of any damages that could result from GOF research into the price of the grant being considered.

Then they could either require grantees to purchase liability insurance to cover the possible damages from this or, alternatively, require a payment to the state or non-state body to cover the expected cost of that research."

The reasons for seeking international input and harmonization were explored. Christopher Park from the Department of State outlined three objectives for seeking greater interaction, including (i) to get greater clarity as to foreign views on U.S. measures; (ii) to change behavior of individual researchers, perhaps best achieved through international scientific bodies; and (iii) trying to change behavior of other governments, requiring different approaches either through multilateral settings or coalition building. He also noted that if the intent was to address laboratory biosafety issues, it would require engaging one set of actors in associated settings, while a separate community and associated forums would be necessary for addressing biosecurity information risks. Another participant highlighted the importance of engaging the human and animal health communities, given the zoonotic nature of relevant diseases.

Keiji Fukuda from WHO stressed the importance in successful international efforts of a common understanding of the nature of the risk being addressed. He offered the negotiation of the International Health Regulations, the WHO Pandemic Influenza Preparedness Framework, and measures to address antimicrobial resistance as examples. He then suggested that such an international common understanding does not exist with regard to GOF studies of concern and that international engagement might be better focused on reaching a technical agreement on the nature of the risk posed by this research.

Participants also discussed three options for balancing national action against a broader international approach: to act now solely at a national level; to act now at a national level but send a clear message as to the desirability of subsequent international engagement; or to begin working on a full international policy process from the outset. Several participants felt that, given the international nature of the risks being addressed, the first option was not appropriate for GOF research. The same participants suggested that the decision as to whether the second or third approach was more suitable should be based on the resources available, the preexisting levels of international concern, and the level of need for international consensus. Another participant suggested that if sufficient resources could not be secured from the outset, it might be better not to initiate an international process rather than have to abandon it after a short while. Some participants highlighted the value of the Global Health Security Agenda as a model for building an international partnership with opportunities to shape the process.

One question raised during the discussion was who should determine the criteria for classifying research as GOF studies of concern or

for identifying specific research proposals that meet those characteristics. Dr. Selgelid suggested that it might usefully be based upon a mutlilayered analysis with institutional, national, and then international stages—relevant research would be identified at each of these levels and then passed on to the next level for further consideration.

The potential for additional oversight measures for GOF studies of concern to reduce interest in GOF research was raised again. Some participants pointed out that in some cases, such as certain types of research involving human subjects, this was acceptable and appropriate. Gabriel Leung suggested that the longer-term impact would be to discourage scientists from entering into research fields connected to emerging or re-emerging pathogens. This was disputed by others, such as Marc Lipsitch from Harvard University.

Participants also discussed possible reactions by international partners, such as China, if the United States decided to introduce an oversight framework for GOF studies of concern. George Gao felt that China would certainly look closely at such a regime.

5

Summing Up

Harvey Fineberg, chair of the Symposium Planning Committee, explained the plan for the final session. First, he would ask the moderators from the various sessions, all members of the planning committee, to offer their perspectives, summarizing and perhaps adding their own personal comments about key points that were raised in each of the sessions. He then wanted to allow an opportunity for those from the National Institutes of Health (NIH) and the National Science Advisory Board for Biosecurity (NSABB) to raise any issues or topics or questions they would like to address, and to invite further comment from those on the stage and in the audience. Finally, the microphones would be opened for additional comments, suggestions, and ideas that anyone present or listening on the Web would like to include in the record.

Dr. Fineberg invited Charles Haas ("Informing the Policy Framework: The Risk and Benefit Assessment") to give the first summary comments. Dr. Haas began with one editorial comment. Data gaps, particularly on laboratory safety, were thought to limit the ability to do an absolute risk assessment, and there had been a good set of questions from the floor about the need to develop scholarship and support for those studies. His comment was that such data are not totally absent, and it might have been informative to use whatever data were available, even though they were poor, as part of the effort to bound the potential risks that could occur.

Dr. Haas also commented that, if a pure "risk acceptable" rule is to be used as a basis for decision making, it should be recognized that information is lacking on what the level of acceptability should be. Rocco

Casagrande had presented an updated analysis using new data on seasonal versus 1918 influenza, which raised the broader point that risk assessments in general need to be living and to be adaptable to new information as it comes along. Dr. Haas also cited Adam Finkel's statement that leaving uncertainty out is a violation of first principles.

He quoted Dr. Finkel that "Is it safe?" is a vapid question because it is intrinsically without meaning without a reference level. A hierarchy of potential judgment rules exists. Both Tony Cox and Dr. Finkel made that clear, and also that explicit judgments about what rule is to be used need to be made. Kara Morgan called this "deciding how to decide," and she noted that there is rich scholarship from the decision analysis community that needs to be brought to bear. And stakeholder input needs to be included to develop the decision rules.

Dr. Cox had cited the need to avoid the "fallacy of coherence": Just because risk has been accepted in the past does not mean that an informed judgment going forward would make that same numerical risk acceptable. A useful task would be to assess whether or not collection of more information would make a decision better. There is a rich literature on the concept of the value of information in this regard.

Dr. Haas concluded by citing a number of miscellaneous problems that had come up in the discussion. For example, Dr. Casagrande had expressed the concern that bench researchers may not be familiar enough with epidemiological parameters to assess transmissibility. Next, risk–benefit analysis could be used to improve the risk profile of proposed experiments—in other words, envisioning an iterative process of some sort. Dr. Finkel had argued that risk and benefit analyses should be balanced, humble, and explicit about value judgments. And finally, there had been comments from the audience that particularly long-term benefits may be difficult to value and highly uncertain. His editorial comment in response was that, while this may very well be true, it should not mean that one should walk away from the effort to attempt to quantify them using whatever information one had available.

Barry Bloom shared reflections from two sessions, first on behalf of Michelle Mello ("The Policy Landscape: United States") and then from the panel he had moderated ("The Policy Landscape: International Dimensions of Gain-of-Function [GOF] Research"). Dr. Mello's comments included:

- There is no set of policies that targets the specific group of pathogens defined by the NSABB. Instead, the federal policy framework consists of a series of partially overlapping statutes and regulations that are largely tied to specific pathogens and to federal research funding. None of the panelists pointed to major gaps in this framework other than noting that the Department of

Health and Human Services targets a *very* narrow set of experiments and the dual use research of concern (DURC) policy covers only 15 pathogens. However, their comments did reinforce the NSABB's observation that the strength of the policy oversight is stronger for some pathogens than for others.

- Existing law does not really reach research that is not conducted with federal funding (i.e., industry-sponsored research). This raises the question, should it? And if so, through what mechanism?
- The time to regulate is at the time the research is conceived. The point of publication is far too late. Having a strong review process up front avoids a lot of problems down the line—and also establishes that institutions have acted with due care (which may come up in litigation). Funding agencies and institutions can engage principal investigators (PIs) at the point of designing their protocols to think through the risk issues. This is especially useful because many PIs do not understand dual use risk issues.
- Regulators, including both institutions and federal agencies, can benefit from greater use of consultation. Talking with each other and with external experts can boost the quality of review and the dissemination of knowledge and best practices.
- Epistemological question: How do we know if a regulatory approach is working? Beyond the absence of rare, catastrophic events, what should we use as performance measures? The panelists suggested public trust, but in her view, this is both hard to assess and a narrow measure. The NSABB may wish to think (in relation to its Key Finding 2) about what it means to say the policy frameworks are "effective."
- One tension in oversight is between the desire for transparency and the risk that public disclosure of sensitive information will elevate the very dual use risks that oversight is aiming to minimize.
- The criteria that the NSABB set forth for reviewing GOF research are reasonable, but not very specific. They rely on subjective judgments such as "likely" and "highly." Yet there is a tension between pursuing greater specificity in regulations and providing enough flexibility to make case by case judgments. Also, it is not clear how to get more specific about some of these standards.
- How much variation should be tolerated in how institutional review committees evaluate research? On the one hand, one would like to have common standards applied in a reliable fashion. On the other hand, institutions have different capacities, and there might be something one can learn from their individual innovations in practices. The panelists did not see a major prob-

lem with having a "patchwork of institution-dependent rules"; this is something the NSABB may wish to consider.

Dr. Bloom then turned to the comments on the session he had moderated ("The Policy Landscape: International Dimensions of GOF Research"). It was clear from the very beginning of the sessions on the first day that everyone involved in this meeting recognizes that science and the risks and benefits have global implications, and GOF research clearly has raised global concerns. The session included major presentations on the groundbreaking progress made by the European Union (EU), which showed that it was possible to have discussions and bring policies from 28 countries to a common focus, and bring scientific academies in almost all of those countries to a consensus on the scientific policies that would govern this research. The discussions emphasized the need to expand and extend the discussion among countries in Europe. The panelists would be very interested in discussions after the U.S. policies are formulated, and they were eager to find out ways in which discussion and consultation can be expanded to include all countries.

In this context, the session heard a very important discussion of the InterAcademy Partnership, a global network of science and medical academies that now links academies in 128 countries and four regions. That could serve as a useful focus for extending the discussions of GOF research in a coherent way to responsible scientific bodies that already exist and perhaps should be considered in moving forward.

A suggestion that emerged from the session was that the best place to start is probably with discussion within the scientific community rather than going directly to policy makers one at a time, one country at a time, until there is some general understanding and agreement within the scientific community. Then the complexities of those dialogues and discussions could be simplified to a level that could gain understanding and support from political leaders.

The session also heard about the value of not just pontificating but having important partnerships and collaborations that enable transparency, technology transfer, and training to occur. These can also be a way of maintaining standards and identifying low standards that need to be addressed.

He offered several personal reflections about what he had learned during the meeting.

- He had come to the view that process is probably as important as principles. It is not clear, given the technicalities of the science, that the lay public, and even government officials, are going to understand the technicalities. But if the processes at every level

are transparent, maybe that is the best way to gain trust within the scientific community and within the public at large. And that means the processes as he was conceiving them, and as the NSABB conceives them, are a set of tiered processes that occurs at multiple levels from the investigator, the Institutional Biosafety Committee (IBC), the institutions, study sections, and all the way up to the higher levels of policy.

- His second reflection on the meeting is that whatever one does, it has to be recognized that science is changing dramatically so that policies cannot be fixed in time to predict what possibilities, opportunities, technologies, and threats will be coming in the future. The policies need to be flexible in some way to accommodate new knowledge and adapt to new opportunities and possibilities and yet have a clear-cut framework that people can work with.
- Finally, he supported Gabriel Leung's comment about why the Biological Weapons Convention (BWC), as far as we know, largely works. Why do the Helsinki principles actually govern how human experimentation is done? He would say it is less legal liability and lawsuits than it is to ask, what are the principal constraints on scientists? He believed those have to do in general with constraints on reputation, credibility, integrity, and respect in the scientific community. Matthew Meselson, for example, when asked how one could possibly encourage more action to enforce the BWC, raised the interesting possibility of making it impossible for scientists who violated international law to travel overseas as another constraint that would be of high value for scientists. So he believed enforcement at a moral level is highly possible.

Baruch Fischhoff offered his comments on the session devoted to "Informing Policy Design: Insights from the Science of Safety and the Science of Public Consultation." He began with some nomenclature, using the term "social science" for those not familiar with that part of the world to include social, behavioral, and decision science. Behavioral science is the study of individuals; it is psychology, microeconomics, neuroscience, and other social sciences. For larger groupings, it is sociology, anthropology, and political science. And decision science is management science, the cost, risk, and benefit analysis of that form of applied mathematics that takes human behavior into consideration. For problems of this complexity and subtlety, he argued that insights from all these fields are needed.

The framing of the human dimensions that he believed came out of the session is that reducing the risks and realizing the benefits of these technologies depends on people at the level of individuals, organizations,

and policies. Second, relying on intuition in designing and evaluating the systems that deal with these technologies is natural, but it is unfortunate because those intuitions are often wrong or imprecise. Third, the biological research community faces the challenge of not having what some economists call the absorptive capacity for social science. That is, there is nobody on the inside who can tell when they have a social science problem, define it in terms that would be recognizable to a social scientist, and find somebody who will help them to work on the problem. That is on the demand side. On the supply side, the social science community may lack the incentives for addressing biological science issues because its incentive scheme is to publish on relatively narrow topics. He thought the symposium was fortunate to have speakers in his session who have that bridge which requires them to draw on different social sciences as well as to see the value for the basic science to engage in applied problems.

He then asked what kinds of issues one would find if one brought the social sciences to bear? One is to identify the places in which scientific judgment affects the prediction of outcomes. Many of the statements heard during the symposium had to do with scientists anticipating how transmissible something would be. Given that this a discovery process, there are likely to be surprises. So it is smart to recognize that these are scientific judgments and to elicit them in the best, most accountable way possible. Second, these are ethical judgments and analyses: for example, how you define them, who you share them with, where various publics are engaged in the process. Third is the communication to and from stakeholders so that one can develop the technologies in the ways that are most sensitive to their needs and keep them properly apprised of developments.

A fourth problem, more from the social sciences, is the normalization of pathology and the virtue. One can become accustomed to best practices that are terrible by any absolute standard. But as Ruthanne Huising's talk and Dr. Bloom's comments illustrate, there is also the possibility of the normalization of virtue. There are things that one just does not do, and this is part of the kind of bottom-up process of acculturation and socialization that Dr. Huising discussed.

Fifth, there can be a mismatch between the technology and the regulatory mechanisms in terms of not just government regulation but also the societal controls that one has over technologies. One can have regulatory control mechanisms that do not have the requisite variety for technology that is moving very quickly when institutions were developed for a different environment. Another problem that one runs into is the neglect of opportunity costs. A good deal is known about the technologies in which one has invested and much less about the ones in which one has not invested.

Dr. Fischhoff concluded, in the spirit of Dr. Bloom's two personal comments, with two recommendations.

- Given the difficulty of bridging the basic and social sciences, there would be value in creating centers that would serve as a kind of clearinghouse for helping interested biologists to find social scientists who could help them work with their problems and social scientists to find the people with whom they are willing to work. They could help make the case to department heads that this is a worthy pursuit to spend as much time as all three of the speakers have had working with clients to apply the social science that is available and to create the needed evidence for what some people call adaptive management.
- The second is to develop shadow alternative evaluation processes. That is, if current mechanisms are not up to it, alternative mechanisms are needed. Monica Schoch-Spana's talk illustrated the potential to bound the set of deliberative mechanisms whereby this might work. But one will not really know how they would work until people with the different kinds of expertise and cultural experiences come together and explore them. And one might hope that if there were some worked examples—maybe like some of the conventions that people have talked about—they would eventually become the normal thing that people do. It is very hard to get people to repeal regulations that promise safety, but sometimes they just atrophy. And maybe they will go away if we have something better.

Philip Dormitzer offered his reflections on the ideas raised by what Dr. Fineberg called the "interested parties" in his session ("Best Practices to Inform National Policy Design and Implementation: Perspectives of Key Stakeholders in the Biomedical and Public Health Communities"). He began with Michael Callahan, who pointed out that the European Union and the United States are not the future epicenter—and may not even be the present epicenter—of GOF research. And similarly, government funding may not necessarily be the dominant mode of funding for this research. It is necessary to expand the thinking about how one might influence these processes. Another very interesting point was that some of the case studies he offered where mechanisms of control of infectious agents of concern were lost not due to any malicious intent but due to the necessities facing people operating under difficult circumstances. There are circumstances where consultative mechanisms might help, where forms of assistance might help, and also where incentives need to be created to encourage people to limit risks when there is no capacity to regulate their behavior.

Robert Fisher had discussed the inherent conflict between the need for evidence-based decision making at the regulatory level, which is necessarily time consuming and expensive, and the frequent need to act quickly, particularly in these emerging or outbreak situations. This conflict has to be reconciled, and the considerations around policy for GOF studies of concern play into that. And this also raised the earlier point that estimation of risk can really only be judged in a context of expected benefit. Without benefit, why would one take any risk? These things play into the sorts of mechanisms that one might pursue to try to control the risks of GOF studies of concern.

Dr. Dormitzer commended Jonathan Moreno for trying to identify where there are areas of consensus regarding policy for GOF research. He did not know if everyone agreed on those areas of consensus, but he thought they were close enough to be worth mentioning. There is consensus that there are times when it is necessary to move quickly, but also that some regulation is needed. There is consensus that biocontainment is imperfect, that risk mitigation heavily involves human factors, especially as the mechanical and environmental factors get under better control. He thought that there was consensus it would be desirable to have alternatives to risky experiments, and that gain of function experiments are not fully predictable, but the capacity is probably improving.

Dr. Moreno also had a very interesting proposal for what he called R-BATs, or Risk–Benefit Assessment Teams. The idea is that there would be real-time, ongoing, interactive evaluation of experiments of concern or experiments that may not yet be of concern but could venture into that area so that there was not simply a checkpoint—for example, at the time of funding and another at the time of publication—but an ongoing process of interaction. Dr. Dormitzer thought that might not take care of the whole issue, but it could make a very solid contribution.

Finally, Ethan Settembre had discussed some of the lessons of the first H1N1 pandemic in 2009 and then the H7N9 outbreak response in 2013, making the point that GOF research is an inherent part of the routine business of vaccine production. Unintended consequences of GOF policy choices therefore needed to be considered.

Dr. Dormitzer noted that today sequence analysis is a part of risk analysis and vaccine virus selection, but it is secondary at this point to phenotypic, clinical, and epidemiologic characterizations. He thought, however, that will start to shift over time. It is certainly never going to be the case that a sequence analysis can replace current approaches, but the volume of relevant sequence data is likely to increase dramatically. It is now possible to sequence flu strains directly from harvested secretions; there is no need to grow the virus. The ability to do that sequencing is becoming increasingly widespread, and it is quite con-

ceivable that these will be done in some sort of handheld devices in the coming decade.

Dr. Dormitzer closed with some personal observations. One was an increasing need to consider integration of the multiple biosafety and biosecurity regimens. The other was a concern about unintended consequences: for example, from the "blowback" onto vaccine production from the controversies over GOF studies of concern—or GOF research more generally—in academia.

Ronald Atlas began the discussion of the session he had moderated ("International Governance: Opportunities for Harmonizing GOF Research Policy and Practice") by remarking that he had learned that the international dimensions of the debate about GOF research, risks, and benefits cannot be ignored. A number of possible ways of approaching that on an international scale had been suggested. One was to go to a non-regulatory framework to take ethics or other sorts of systems that have gained traction and are accepted across the biomedical field, build on those, and essentially build a culture of responsibility within the community that would assure the public that everyone was taking the appropriate mitigation steps. Another was to simply accept that nations that were carrying out GOF research would develop their own sets of regulatory frameworks. Another was to allow the efforts that are ongoing in areas like the United States and the European Union to begin to cross-fertilize each other and to bring together groups that would then allow for voluntary harmonization without going to an international organization like the World Health Organization (WHO). And finally, the higher level is to go to a United Nations agency such as WHO and attempt the perhaps impossible task of coming up with a global regulatory scheme.

Dr. Atlas thought that another important point from the session came from Keiji Fukuda: the need to find a compelling and readily understood reason to come together at the international level to take action. What would that reason be for GOF research? Dr. Atlas suggested that it could be "preventing a global pandemic." That could mean that the research is absolutely necessary because it will provide the vaccines, the surveillance, or whatever to prevent the pandemic. Or to take the opposite side, the research itself is a risk because something could get out and cause a pandemic. That is the dilemma underlying the entire debate over GOF research, and he was still not sure there would ever be an answer that was satisfactory to everyone.

Dr. Fineberg then asked if any NSABB members had comments or questions. Joseph Kanabrocki from the University of Chicago and co-chair of the NSABB WG began with some observations. He was heartened that the comments and discussion suggested that the NSABB had not made any major missteps. He was also pleased that there was movement away

from a list-based system to a phenotypic system that the NSABB has been recommending for a number of years. That had not been explicitly stated but he thought it was implicit in the discussions.

Dr. Kanabrocki said that, speaking personally, he had heard a number of things on which the NSABB WG had not yet deliberated that he would like to see added to the NSABB report. These included incident reporting mechanisms that could address the lack of data highlighted by the risk and benefit assessment as well as the need for harmonization, both on the national level and the international level. He thought it should be something the final report called for more explicitly, and addressed some of the ideas about how that could be accomplished. He also hoped that the NSABB would recommend a code of conduct for scientists engaged in this type of research.

Dr. Kanabrocki then returned to the three phenotypes recommended in the draft report as the criteria for identifying GOF studies of concern. The original version of the NSABB WG's Draft Working Paper included resistance to countermeasures as an example. He stressed that it was intended only as an example, but, unfortunately, people seemed to have seized on it as the one aspect of the third criterion. So he wanted to remind everyone that for him—and he thought most of the NSABB as well—the third phenotype is what makes this an issue of pandemic potential. He thought the first and second traits go to the animal pathogen interface, and the third trait is where one addresses human public health, the societal aspects of pandemic. He thought that the third trait remains critical, though it might be possible to revise the language in a way that is more palatable.

Susan Wolf, an NSABB member from the University of Minnesota, raised the issue of oversight design and said she wanted to try out two ideas, one at the institutional and one at the federal level. This is crystalized by the flow chart introduced at the symposium (see Figure 2-2). The NSABB has developed the chart to communicate visually the oversight process it is planning. At the institutional level, who decides that an experiment is a potential GOF study of concern? At the moment, the NSABB is envisioning the initial determination would be made by the PI and the local oversight authorities, presumably the IBC. Her concern was how to avoid recapitulating the history of Institutional Review Boards (IRBs), which she characterized as being very slow to design, much less to put in place the sort of "learning" oversight system where there is a systematic effort to gather experience and share lessons learned and also to identify unjustified variations in how the rules are applied. There is a substantial amount of research on this problem and she hoped it would be applied to ensure that the GOF system would be state of the art.

Her other concern was at the federal level and what would happen if a GOF study of concern is identified at the local level. Who would review

it and apply the several principles the NSABB was proposing? Could one answer be a new Federal Advisory Committee Act (FACA) committee charged with this task?

Marie-Louise Hammarskjöld, an NSABB member from the University of Virginia, asked about the issue of how to capture research done without federal funding, citing increased interest from industry in university research. She thought that, given that the concern was potential pandemic risk, the board might not be doing its job if it did not deal with that part of the research enterprise.

Jim LeDuc, an NSABB member and Director of the Galveston National Laboratory at the University of Texas Medical Branch, was particularly interested in risk mitigation. His question to the panel was how to create a foundation upon which a policy can be built that clearly articulates the requirements for biosafety and biosecurity, and importantly, a culture of responsibility that spans the scope from the individual scientist all the way through to the institutional leadership.

Dr. Atlas reacted to the question of the IBC versus the national level and suggested that a great deal was learned during the early days of the Recombinant DNA Advisory Committee (RAC). He commented that the IBCs sent cases to the full national board until the RAC was able to demonstrate to the local IBCs what was and was not of greater concern. The RAC refined the principles, and he thought the same approach should be taken for GOF studies of concern. What is needed is to create a learning process, an iterative process, where there is appropriate consultation from the national back to the local and eventually the local learns how to handle the cases and the burden on the national board diminishes.

The RAC had also dealt with the question of federal funding. It turned out that the first cases that came to the RAC were from industry, which wanted the national approval. Industry did not want to go around the system; it wanted to become part of the system even though it was not mandated to do so. He had no reason to think the same thing would not happen here.

Dr. Dormitzer said that he could certainly speak for having been in companies when there are national and accepted standards. Even when not required to follow them, companies in general want to do so. In fact, the most distressing situations are those where there is a lack of clarity over what the expectations are. And that is why the ideas about advisory boards and groups to which companies can turn to ascertain what those standards are, even if compliance is voluntary, are useful. He thought there would be a widespread desire to meet the standards.

Dr. Fineberg added a comment about the discussion of the importance of the scientific community building and reinforcing a culture of safety as well as a discussion about the importance and practicality of public

engagement and about the various types of publics. It seemed to him that in the thinking of the NSABB, going forward it would be useful to consider a model that incorporates, at an appropriate level, a FACA-like entity and relevant public participation as a way of building the kind of larger trust, and, frankly, reinforcing the community of safety, both within and around the scientific community, on which success ultimately will depend.

Dr. Fischhoff commented that he was involved with the Food and Drug Administration (FDA) over the past few years as the Center for Drug Evaluation and Research developed a benefit–risk framework (FDA, 2013). The framework was developed jointly with its staff and resembles Kara Morgan's model of deliberative criteria-based frameworks (see Box 2-3). It was designed to help people tell their story in a way that one could see what the logic was; one could compare across decisions; and one could find the decisions that were—as someone has mentioned—anomalous and that gave industry a clearer sense of the kind of things that the FDA was approving.

Dr. Fineberg made another observation on the first and fundamental question of the phenotypic inclusiveness or exclusiveness. One of the things he heard repeatedly in the course of the discussion was the importance of circumscribing the domain of concern so that neither the scientific community nor the regulatory authority, nor, frankly, the interested publics were needlessly burdened with a wide variety of questions that truly do not raise and rise to a level of concern. At the same time, there was a lot of discussion as to whether the current formulation—where the requirement is that a given experiment affects all of the elements—is a sufficient degree of circumscription. He thought that the real challenge for the NSABB was to reflect its actual intent in its description and to do so in a way that is clear and understandable over time. So, for example, he thought that one could be overly fixed on the models that depend on familiarity with influenza as the case. He thought the policy that will be promulgated ultimately needs to be capable of dealing with GOF research, and increasingly, experiments that intend to develop entirely novel organisms with capacities and capabilities that are not currently even expressed in existing microorganisms. And if one thinks that broadly, defining a phenotypic space that involves virulence, and involves transmissibility, and involves resistance to treatment, if that is how one wishes to characterize it, one could imagine placing imaginably any organism at a point in space that has those three attributes defined. Thought of that way, there is an aspect of this space where one would not want research to go at all. There is an aspect of that space where one would not want to require further review. And then there is an aspect of that space, depending on the starting point and the direction of the experiment to make it worse or to make it

better—and this is where vaccine development comes in so importantly—would dictate that it may, then, be a topic that requires consideration as a GOF study of concern. He said he hoped that it would be possible for the NSABB to mull over this question and to think about ways to characterize and describe exactly what it believes should determine a consideration for GOF studies of concern. And, perhaps, to be explicit about excluding vaccine development research, which is so fundamental to protection and actually contrary to the concerns. And to be able to apply the principles more generally as new ideas with different organisms will naturally arise in the creative minds of scientists.

Dr. Kanabrocki agreed and said that he wanted to clarify again that, as his NSABB WG co-chair Ken Berns had said on the first day, the NSABB was not really worried about what goes in, but what comes out. The NSABB WG was not saying that the experiments of concern are only those that would result in the three phenotypes. What they were saying is the experiments of concern are those that result in an organism that displays those three phenotypes, and there is a difference. Because one could begin with two of the three and contribute the third and that would be an experiment of concern.

Dr. Fineberg then opened the floor to questions and comments from the participants. Wendy Hall from the Department of Homeland Security asked a question in terms of precedent. First, how important is it that one has full awareness of the GOF experiments being proposed throughout a variety of different labs in the United States? She was not sure there is clarity across the academic community at any one point in time about who is planning and doing what. Her second question related to the experience with the Select Agent rules, which were implemented in 300 various labs with a substantial range in the quality of performance. In GOF research, is there any precedent—if the academic community had full visibility, peer to peer, institution to institution—that there could be corrective elements from the institutional bodies with each other to redirect or help labs not performing as well? Her hope was to avoid the need for the government to have to come down with tough, restrictive language across the board that affects everyone because of a case where one or two labs make an error that makes the mainstream press.

Dr. Fineberg responded that her question reinforced the importance of the scientific community itself coming together in a coherent way on this and related issues of safety and security. From a personal point of view, he did not think the government alone could accomplish this, nor could the community, acting without the guidance of shared standards. So he thought the efforts would be mutually reinforcing.

Dr. Schoch-Spana from the Center for Health Security of the University of Pittsburgh Medical Center picked up a point that Marc Lipsitch from

Harvard University had made about the capacity for innovation, not just prevention. Are there things, such as special research funds, that could incentivize scientists to try alternative approaches to GOF studies of concern? If systems are put in place and data are gathered about the kinds of experiments that are not funded, those data could be synthesized to identify lines of work that need to be replaced with safer alternatives, and research to develop those alternatives could be eligible for special funding.

Nicolas Evans from the University of Pennsylvania offered two comments. The first concerned the Declaration of Helsinki, which was a great initial work in establishing norms in human subjects research and biomedical ethics. But he thought that the FDA's removal of the Declaration of Helsinki from its regulations was an indicator that, as a model for governing the life sciences, one should be especially careful about the way one seeks international collaboration. If the United States sets up or attempts to initiate other arrangements for governing GOF research, only to pull out of them because it does not want them referenced in its own legislation, that would pose a major problem. He also built on Dr. Lipsitch's and Susan Wolf's comments about the critique that IRBs and biomedical ethics chill biomedical research, commenting that it had been made many times and citing two recent works (Klitzman, 2015; Schneider, 2015).

Dr. Evans also offered three other comments.

- He thought it was very important conceptually to make a clear distinction between general GOF research, which is accepted as a valuable and commonly used technique, and specific GOF experiments resulting in the creation of novel pandemic pathogens that is beneficial. For example, the Gryphon Scientific benefits assessment had concluded that a portion of the studies it assessed provided unique benefits.
- Dr. Evans noted that health care workers, the people who bear the disproportionate burden of risk in the event of an infectious disease outbreak, had been entirely absent from the discussions.
- Regarding innovation, he commented that because $820 million had been provided to synthetic biology research over the past half decade, it seemed prudent to also spend a small amount of money on innovation in applied biosafety, such as on material science to improve personal protective equipment.

Jenna Ogilvie from the National Academies of Sciences, Engineering, and Medicine's staff brought two questions from the Web. The first was from Grigory Khimulya from Harvard College. Do current oversight frameworks provide adequate treatment of novel pathogens that

were never seen before and are not on the pathogen lists mentioned in the NSABB's draft recommendations? For example, if a new potentially pandemic pathogen like Middle East respiratory syndrome (MERS) is identified, would GOF studies of concern with this pathogen fall under proposed regulation? The second question, to Dr. Casagrande from Gryphon Scientific, came from John Kadvany from Policy & Decision Science in Menlo Park, California, prompted by publications suggesting that GOF research has characteristics of so-called potential "normal accidents," in which a technology combines highly negative outcomes (e.g., a nuclear plant meltdown) with unquantified and perhaps unquantifiable scenarios falling outside even the most complete probabilistic risk analysis. Gryphon Scientific's work suggests that such scenarios may be relevant with the extreme negative outcome being pandemic risk. Did Dr. Casagrande have an opinion on this characterization of GOF studies of concern? Is it correct in some respects as it may be for some contemporary technologies? Or is there a characterization fueling clashing GOF risk perceptions?

Dr. Casagrande commented from outside his role as PI of the risk and benefit assessment to push back a little bit on several comments he had heard about what could be learned from the successes of the BWC. He thought that the protocol was a better exemplar because it banned first use of bacteriological warfare. In contrast, several members of the BWC have violated its provisions, leading him to conclude that one ought to learn from its failures, such as the lack of a verification and inspection regime and the lack of an enforcement capability that is relevant internationally.

Dr. Lipsitch from Harvard University commented that there had been considerable discussion about whether there is consensus that there are any experiments that everyone would agree would never be acceptable and any experiments everyone would agree should never be impeded. He said he could certainly think of experiments and developments one would never want to impede and suggested that there should be a green line as well as a red line. He thought that whatever regulatory framework or oversight framework is developed, it would be incredibly helpful to have at least those two kinds of cases spelled out by some examples in order to build our intuition for the next time something comes up that is not envisioned yet. He also thought some more contestable case studies, where there would not be an easy consensus, would be useful.

Dr. Kanabrocki responded to Dr. Lipsitch. The NSABB WG had tried on a number of occasions to think of experiments that absolutely should not be done. And every single example that came up was of an experiment that lacked scientific merit. So he suggested that, in his personal view, it would be a struggle to think of experiments that have scientific merit that should not be done.

Gerald Epstein from the Department of Homeland Security suggested that it would be useful to go back to the Department of Health and Human Services (HHS) framework that Larry Kerr had described on the first day, and the test that a proposed project would have to satisfy before it was deemed acceptable for funding. One was that the pathogen to be constructed was one that might occur by a natural process, so that there was a reasonable expectation nature might get there first. If it is not something nature might do on its own, one could not argue the work was to defend against a potential natural development. This might be an example of something on the other side of the line, at least from the precedent of the existing HHS framework.

Dr. Fineberg closed the session by expressing the Academies' deep appreciation to everyone who had taken part, in person or via the Web. He commended the work being done in Europe and commented that, in his view, a policy about GOF research that applies only to one country is not a policy that will work for the safety of the world. And that is something of which one needed to be very mindful. He also commented that it was evident from all the discussion that whatever the next iteration of conclusions and recommendations that emerge from the NSABB is, it will really be one step in a process that is likely to continue. It will require continued refinement, the engagement of the scientific community, and finding creative ways for the public that is interested and affected by GOF research to be involved in the process of decision making going forward.

Appendix A

Board and Committee Members of Collaborating Units

BOARD ON LIFE SCIENCES

Chair

JAMES P. COLLINS (*Chair*), Virginia M. Ullman Professor of Natural History and the Environment, School of Life Sciences, College of Liberal Arts and Sciences, Arizona State University

Members

ENRIQUETA C. BOND, President Emeritus, Burroughs Wellcome Fund
ROGER D. CONE, Professor and Chairman of Molecular Physiology and Biophysics, Vanderbilt University Medical Center
NANCY D. CONNELL, Professor of Medicine and Director, Center for the Study of Emerging and Re-emerging Pathogens, New Jersey Medical School
JOSEPH R. ECKER, Professor, Salk International Council Chair in Genetics, Salk Institute for Biological Studies
SARAH C. R. ELGIN, Professor of Biology, Department of Biology, Washington University
LINDA G. GRIFFITH, Professor of Biological Engineering, Massachusetts Institute of Technology
ELIZABETH HEITMAN, Associate Professor, Center for Biomedical Ethics and Society, Vanderbilt University Medical Center
RICHARD A. JOHNSON, CEO, Global Helix LLC

JUDITH KIMBLE, Vilas Professor of Biochemistry and Molecular Biology and Medical Genetics, University of Wisconsin, Madison
MARY E. MAXON, Biosciences Principal Deputy, Lawrence Berkeley National Laboratory
JILL P. MESIROV, Professor, Department of Medicine, San Diego School of Medicine and Moores Cancer Center
KAREN E. NELSON, President, J. Craig Venter Institute
CLAIRE POMEROY, President, Albert and Mary Lasker Foundation
MARY E. POWER, Professor, Department of Integrative Biology, University of California, Berkeley
MARGARET RILEY, President, Massachusetts Academy of Sciences; Professor of Biology, University of Massachusetts
LANA SKIRBOLL, Vice President, Academic and Scientific Affairs, Sanofi
JANIS WEEKS, Professor, Department of Biology, University of Oregon

Staff

FRANCES SHARPLES, Director
LIDA ANESTIDOU, Senior Program Officer
KATIE BOWMAN, Senior Program Officer
JO HUSBANDS, Senior Scholar
JAY LABOV, Senior Scholar
KEEGAN SAWYER, Program Officer
MARILEE SHELTON-DAVENPORT, Senior Program Officer
AUDREY THEVENON, Associate Program Officer
BETHELHEM MEKASHA, Financial Associate
VANESSA LESTER, Research Associate
ANGELA KOLESNIKOVA, Administrative Assistant
JENNA OGILVIE, Senior Program Assistant
AANIKA SENN, Senior Program Assistant

BOARD ON HEALTH SCIENCES POLICY

Chair

JEFFREY KAHN (*Chair*), Levi Professor of Bioethics and Public Policy, Johns Hopkins University

Members

WYLIE BURKE, Professor and Chair, Bioethics and Humanities Department, University of Washington
R. ALTA CHARO, Warren P. Knowles Professor of Law and Bioethics, University of Wisconsin, Madison
LINDA H. CLEVER, Senior Physician, Occupational Health, California Pacific Medical Center; President, RENEW
BARRY S. COLLER, Physician in Chief, Vice President for Medical Affairs, and David Rockefeller Professor, The Rockefeller University
BERNARD A. HARRIS, CEO and Managing Director, Vesalius Ventures
MARTHA N. HILL, Dean Emerita and Professor of Nursing, Medicine and Public Health, Johns Hopkins University School of Nursing
STEVEN E. HYMAN, Director, Stanley Center, The Broad Institute
ALAN M. JETTE, Professor of Health Policy & Management, Boston University School of Public Health
PATRICIA A. KING, Carmack Waterhouse Professor of Law, Medicine, Ethics and Public Policy, Georgetown University Law Center
STORY C. LANDIS, Scientist Emeritus, National Institute of Neurological Disorders and Stroke
HARRY T. ORR, Director, Institute of Human Genetics, University of Minnesota
UMAIR SHAH, Executive Director, Harris County Public Health & Environmental Services
ROBYN STONE, Senior Vice President of Research, LeadingAge
SHARON TERRY, President and CEO, Genetic Alliance

Board Director

ANDREW M. POPE, Senior Board Director

COMMITTEE ON SCIENCE, TECHNOLOGY, AND LAW

Co-Chairs

DAVID BALTIMORE, President Emeritus and Robert Andrews Millikan Professor of Biology, California Institute of Technology

DAVID S. TATEL, Judge, U.S. Court of Appeals for the District of Columbia Circuit

Members

THOMAS D. ALBRIGHT, Conrad T. Prebys Chair in Vision Research, Salk Institute for Biological Studies

ANN ARVIN, Lucile Packard Professor of Pediatrics and Microbiology and Immunology; Vice Provost and Dean of Research, Stanford University

BARBARA E. BIERER, Faculty Co-chair, Multi-Regional Clinical Trials Center, Harvard University (Harvard MRCT), and Professor of Medicine, Harvard Medical School and Brigham and Women's Hospital

CLAUDE CANIZARES, Bruno Rossi Professor of Physics, Massachusetts Institute of Technology

ARTURO CASADEVALL, Professor and Chair, W. Harry Feinstone Department of Molecular Microbiology and Immunology, Johns Hopkins Bloomberg School of Public Health

JOE S. CECIL, Project Director, Program on Scientific and Technical Evidence, Division of Research, Federal Judicial Center

R. ALTA CHARO, Warren P. Knowles Professor of Law and Bioethics, University of Wisconsin, Madison

HARRY T. EDWARDS, Judge, U.S. Court of Appeals for the District of Columbia Circuit

DREW ENDY, Associate Professor, Bioengineering, Stanford University, and President, BioBricks Foundation

MARCUS FELDMAN, Burnet C. and Mildred Wohlford Professor of Biological Sciences, Stanford University

JEREMY FOGEL, Director, Federal Judicial Center

HENRY T. GREELY, Deane F. and Kate Edelman Johnson Professor of Law and Professor, by courtesy, of Genetics, Stanford School of Medicine

MICHAEL GREENBERGER, Law School Professor and Director, Center for Health and Homeland Security, University of Maryland

MICHAEL IMPERIALE, Arthur F. Thurnau Professor of Microbiology and Immunology, University of Michigan

GREG KISER, Chief Technologist, Intellectual Ventures

ROBERT S. LANGER, David H. Koch Institute Professor, Massachusetts Institute of Technology
GOODWIN, LIU, Associate Justice, California Supreme Court
JENNIFER MNOOKIN, Dean, and David G. Price and Dallas P. Price Professor of Law, University of California, Los Angeles, School of Law
R. GREGORY MORGAN, Senior Vice President and Secretary of the Corporation, Massachusetts Institute of Technology
HARRIET RABB, Vice President and General Counsel, The Rockefeller University
DAVID A. RELMAN, Thomas C. and Joan M. Merigan Professor, Departments of Medicine, and of Microbiology and Immunology, Stanford University and Chief, Infectious Disease Section, Veterans Affairs Palo Alto Health Care System
MARTINE A. ROTHBLATT, Chairman and Chief Executive Officer, United Therapeutics
JOSHUA R. SANES, Professor of Molecular and Cellular Biology and Paul J. Finnegan Family Director, Center for Brain Science, Harvard University
DAVID VLADECK, Professor and Co-Director, Institute for Public Representation, Georgetown Law School

Staff

ANNE-MARIE MAZZA, Director
STEVEN KENDALL, Program Officer
KAROLINA KONARZWESKA, Program Coordinator

Appendix B

Committee Biographies

Harvey V. Fineberg (*Committee Chair*) is the president of the Gordon and Betty Moore Foundation and served two consecutive terms as president of the Institute of Medicine (IOM) (2002-2014), now known as the National Academy of Medicine. He served as provost of Harvard University from 1997 to 2001, following 13 years as dean of the Harvard School of Public Health. He has devoted most of his academic career to the fields of health policy and medical decision making. His past research has focused on the process of policy development and implementation, assessment of medical technology, evaluation and use of vaccines, and dissemination of medical innovations. Dr. Fineberg helped found and served as president of the Society for Medical Decision Making and has been a consultant to the World Health Organization. At the IOM, he chaired and served on a number of panels dealing with health policy issues, ranging from AIDS to new medical technology. He also served as a member of the Public Health Council of Massachusetts (1976-1979), as chairman of the Health Care Technology Study Section of the National Center for Health Services Research (1982-1985), and as president of the Association of Schools of Public Health (1995-1996). Dr. Fineberg serves on the board of the Hewlett Foundation and chairs the board of the Carnegie Endowment for International Peace. Dr. Fineberg is co-author of the books *Clinical Decision Analysis*, *Innovators in Physician Education*, and *The Epidemic that Never Was*, an analysis of the controversial federal immunization program against swine flu in 1976. He has co-edited several books on such diverse topics as AIDS prevention, vaccine safety, global health, and understanding risk in

society. He has also authored numerous articles published in professional journals. Dr. Fineberg is the recipient of several honorary degrees and the Stephen Smith Medal for Distinguished Contributions in Public Health from the New York Academy of Medicine. He earned his bachelor's and doctoral degrees from Harvard University.

Ronald M. Atlas is professor of biology at the University of Louisville. After receiving his master's and doctoral degrees from Rutgers University, he became a postdoctoral fellow at the Jet Propulsion Laboratory where he worked on Mars life detection. He has served as chair of the National Aeronautics and Space Administration's Planetary Protection Subcommittee, co-chair of the American Society for Microbiology (ASM) Task Force on Biodefense, and a member of the Federal Bureau of Investigation Scientific Working Group on Microbial Genetics and Forensics. He also served as president of ASM and was a member of the National Institutes of Health Recombinant Advisory Committee. He currently chairs the Public and Scientific Affairs Board of the ASM. His research has included development of detection methods for pathogens in the environment. Dr. Atlas is author of nearly 300 manuscripts and 20 books, and regularly advises the U.S. government on policy issues related to the deterrence of bioterrorism.

Ruth L. Berkelman is the Rollins Chair and Director of the Center for Public Health Preparedness and Research at the Rollins School of Public Health at Emory University. She holds appointments in the departments of epidemiology, global health and medicine, and serves as a senior associate faculty member in Emory's Center for Ethics. She previously served as an assistant surgeon general in the U.S. Public Health Service at the Centers for Disease Control and Prevention (CDC). Elected to the Institute of Medicine (now the National Academy of Medicine) in 2004, she has served on various committees, including the Forum on Emerging Infectious Diseases and the Board on Life Sciences. She has been a member of the National Biodefense Science Board and the Board of Trustees at Princeton University. She was previously Chair of the Public and Scientific Affairs Board of the American Society of Microbiology. She currently chairs the Board of Scientific Counselors for infectious diseases at CDC.

Barry R. Bloom is a leading scientist in the areas of infectious diseases, vaccines, and global health and is a former consultant to the White House. Dr. Bloom enjoyed a distinguished career in bench science as the principal investigator of a laboratory researching the immune response to tuberculosis. He has been extensively involved with the World Health Organization (WHO) for more than 40 years. He was Chair of the Technical and Research Advisory Committee to the Global Programme on

Malaria at WHO and a member of the WHO Advisory Committee on Health Research, as well as chairing the WHO Committees on Leprosy Research and Tuberculosis Research, and the Scientific and Technical Advisory Committee of the United Nations Development Programme/World Bank/WHO Special Programme for Research and Training in Tropical Diseases. Dr. Bloom serves on the editorial board of the *Bulletin of the World Health Organization*. Dr. Bloom served on the Ellison Medical Foundation Scientific Advisory Board and the Wellcome Trust Pathogens, Immunology and Population Health Strategy Committee. He was on the Scientific Advisory Board of the Earth Institute at Columbia University and the Advisory Council of the Paul G. Rogers Society for Global Health Research. His past service includes membership on the National Advisory Council of the National Institute for Allergy and Infectious Diseases, the Scientific Advisory Board of the National Center for Infectious Diseases of the Centers for Disease Control and Prevention, and the National Advisory Board of the Fogarty International Center at the National Institutes of Health, as well as the Governing Board of the Institute of Medicine, now known as the National Academy of Medicine. Dr. Bloom was the founding chair of the board of trustees for the International Vaccine Institute in South Korea. He has chaired the Vaccine Advisory Committee of UNAIDS where he played a critical role in the debate surrounding the ethics of AIDS vaccine trials. He was also a member of the U.S. AIDS Research Committee. Dr. Bloom was introduced to the Harvard Chan School as the Dean of Faculty in 1998, and stepped down December 31, 2008. Dr. Bloom now serves as a Harvard University Distinguished Service Professor.

Donald S. Burke is the dean of the Graduate School of Public Health, director of the Center for Vaccine Research, and associate vice chancellor for global health at the University of Pittsburgh. He is also the first occupant of the University of Pittsburgh Medical Center-Jonas Salk Chair in Global Health and a distinguished university professor of health science and policy. He was an intern and resident in medicine at Boston City and Massachusetts General Hospitals and trained as a research fellow in infectious diseases at the Walter Reed Army Medical Center. Dr. Burke has expertise in the prevention and control of infectious diseases of global concern, including HIV/AIDS, influenza, dengue, and emerging infectious diseases. He is an Institute of Medicine (IOM) member (now the National Academy of Medicine) and has served on previous National Research Council and IOM committees, including the Committee on the Special Immunizations Program for Laboratory Personnel Engaged in Research on Countermeasures for Select Agents and the Committee on Assessment of Future Scientific Needs for Live Variola Virus. Dr. Burke received his B.A. from Western Reserve University and his M.D. from Harvard Medical School.

Philip R. Dormitzer is vice president and chief scientific officer for viral vaccines in the Pfizer Vaccine Research and Development Unit. He is a board certified internal medicine physician. After studying anthropology at Harvard College and carrying out a field study of the Efe Pygmies in the Ituri Forest of Zaire, he completed his M.D. and Ph.D. in Cancer Biology at Stanford University. Dr. Dormitzer completed house-staff training in Internal Medicine at Massachusetts General Hospital and a fellowship in the Harvard Combined Infectious Diseases Training Program. As an assistant professor of pediatrics at Harvard Medical School, Dr. Dormitzer led a structural virology laboratory. The Dormitzer group and its collaborators determined the structures of the rotavirus neutralization antigens by nuclear magnetic resonance spectroscopy, X-ray crystallography, and near atomic resolution electron cryomicroscopy. From 2007-2015 Dr. Dormitzer held a series of positions at Novartis Vaccines and Diagnostics, and was global head of research and vice president at a successor company, Novartis Influenza Vaccines. His teams' research and development programs included vaccines targeting influenza, respiratory syncytial virus, cytomegalovirus, HIV, and parvovirus B19. In 2009, he led the research component of the Novartis response to the H1N1 influenza pandemic, supporting the development and licensure of three pandemic influenza vaccines in the most rapid vaccine response in history. In a Biomedical Advanced Research and Development Authority–funded collaboration with the J. Craig Venter Institute and Synthetic Genomics Vaccines, Inc., the Novartis influenza vaccine research team developed a process to synthesize influenza vaccine seed viruses and deployed the technology in response to the H7N9 influenza outbreak in China. The team's other technology platforms included structurally engineered antigens, adjuvants that target toll-like receptors, and self-replicating messenger RNA vaccines.

Baruch Fischhoff is the Howard Heinz University Professor in the departments of Social and Decision Sciences and of Engineering and Public Policy at Carnegie Mellon University, where he heads the Decision Sciences major. A graduate of the Detroit Public Schools, he holds a B.S. in mathematics and psychology from Wayne State University and an M.A. and a Ph.D. in psychology from the Hebrew University of Jerusalem. He is a member of the National Academy of Medicine and is past President of the Society for Judgement and Decision Making and of the Society for Risk Analysis, and recipient of its Distinguished Achievement Award. He was founding chair of the Food and Drug Administration Risk Communication Advisory Committee and recently chaired the National Research Council Committee on Behavioral and Social Science Research to Improve Intelligence Analysis for National Security. Dr. Fischhoff currently co-

chairs the National Research Council Committee on Future Research Goals and Directions for Foundational Science in Cybersecurity and the National Academy of Sciences' Sackler Colloquium on "The Science of Science Communication." He is a former member of the Eugene, Oregon, Commission on the Rights of Women, Department of Homeland Security's Science and Technology Advisory Committee, the World Federation of Scientists Permanent Monitoring Panel on Terrorism, and the Environmental Protection Agency Science Advisory Board, where he chaired the Homeland Security Advisory Committee. He is a fellow of the American Psychological Association, the Association for Psychological Science (previously the American Psychological Society), the Society of Experimental Psychologists, and the Society for Risk Analysis.

Charles N. Haas is the L.D. Betz Chair Professor of Environmental Engineering and Head of the Department of Civil, Architectural, and Environmental Engineering at Drexel University. His broad research interests include drinking water treatment, bioterrorism and risk assessment. Specific research activities include assessment of risks from exposures to deliberately released agents; engineering analysis and optimization of chemical decontamination schemes; microbiological risks associated with pathogens in drinking water, biosolids, and foods; novel kinetic models for disinfection processes and process control; and use of computational fluid dynamics for process modeling. Dr. Haas was co-director of the Center for Advancing Microbial Risk Assessment that is jointly funded by the Department of Homeland Security and the Environmental Protection Agency. He received his Ph.D. from the University of Illinois. He is a past member of the National Academies of Sciences, Engineering, and Medicine's Water Science and Technology Board. He is currently a fellow of multiple societies, including the American Association for the Advancement of Science, American Academy of Microbiology and Society for Risk Analysis.

Michelle M. Mello is Professor of Law at Stanford Law School and Professor of Health Research and Policy at Stanford University School of Medicine. She conducts empirical research into issues at the intersection of law, ethics, and health policy. She is the author of more than 140 articles and book chapters on the medical malpractice system, medical errors and patient safety, public health law, research ethics, the obesity epidemic, pharmaceuticals, and other topics. From 2000-2014, Dr. Mello was a professor at Harvard School of Public Health, where she directed the School's Program in Law and Public Health. In 2013-2014 she completed a Lab Fellowship at Harvard University's Edmond J. Safra Center for Ethics. Dr. Mello teaches courses in torts and public health law. She holds a J.D.

from the Yale Law School, a Ph.D. in Health Policy and Administration from the University of North Carolina at Chapel Hill, and an M.Phil. from Oxford University, where she was a Marshall Scholar. In 2013, she was elected to the National Academy of Medicine, formerly known as the Institute of Medicine.

Sir John Skehel is a graduate of the University College of Wales, Aberystwyth (1962) and gained his Ph.D. from the University of Manchester (1966). He did research at the University of Aberdeen (1965-1968) and was a Helen Hay Whitney Foundation fellow at Duke University and at the Medical Research Council (MRC) National Institute for Medical Research (NIMR) Mill Hill (1968-1971). He was MRC staff scientist at NIMR from 1971 to 2006, Director of the World Health Organization World Influenza Centre from 1975 to 1993, Head of Infections and Immunity from 1985 to 2006 and Director of the NIMR from 1987-2006. He is a visiting scientist in the Division of Virology at The Crick Institute. His research is on the influenza virus hemagglutinin and neuraminidase membrane glycoproteins and the mechanisms of their receptor binding, membrane fusion and enzymic activities. He is a Trustee of the Animal Health Trust. He was elected member of the European Molecular Biology Organization in 1983, fellow of the Royal Society in 1984, member of the Academia Europaea in 1992 and fellow of the Academy of Medical Sciences in 1998 (vice president from 2001-2006) and a foreign associate of the United States National Academy of Sciences in 2014. He was knighted in 1996. He was honorary professor of virology at Glasgow University, Liverpool John Moores University in 2007 and University of Padua (medicine and surgery) in 2010. He is a fellow of the University of Wales and an honorary member of the Society for General Microbiology.

Appendix C

Symposium Agenda

National Academy of Sciences Building
2101 Constitution Avenue NW
Washington, DC 20418
March 10-11, 2016

Thursday, March 10: Overview and Context

8:00 am **Registration**
(coffee and tea will be served)

8:45 **Welcome and Opening Remarks**
Moderator: Harvey Fineberg, Symposium Planning Committee Chair

Ralph J. Cicerone, President, National Academy of Sciences
Margaret Hamburg, Foreign Secretary, National Academy of Medicine
Jo Handelsman, Office of Science and Technology Policy
Carrie Wolinetz, National Institutes of Health

9:15 **Overview of the Draft NSABB Policy Framework and Key Policy Questions**
Moderator: Harvey Fineberg, Symposium Planning Committee Chair

Overview of the NSABB Working Paper
Samuel Stanley, Stony Brook University and NSABB Chair
Harvey Fineberg, Symposium Planning Committee Chair

Open Discussion

10:45 **Break**

11:15 **Informing the Policy Framework: The Risk/Benefit Assessment**
Moderator: Charles Haas, Symposium Planning Committee Member

Lessons from the Risk/Benefit Assessment
Rocco Casagrande, Gryphon Scientific

Comments
Louis (Tony) Cox, Cox Associates
Adam Finkel, University of Pennsylvania
Kara Morgan, Battelle

Open Discussion

12:45 pm **Lunch**
(seating available in the West Court and Members Room - follow signs)

1:45 **The Policy Landscape: United States**
Moderator: Michelle Mello, Symposium Planning Committee Member

Discussants
Gerald Epstein, Department of Homeland Security
Richard Frothingham, Duke University
Lawrence Kerr, Department of Health and Human Services
Philip Potter, St. Jude Children's Research Hospital

Open Discussion

3:15 **Break**

3:45 **The Policy Landscape: International Dimensions of GOF Research**
Moderator: Barry Bloom, Symposium Planning Committee Member

Discussants
Ruxandra Draghia-Akli, European Commission
Keiji Fukuda, World Health Organization

Volker ter Meulen, European Academies Science Advisory Council
Silja Vöneky, University of Freiburg and German Ethics Council

Open Discussion

5:15 **Adjourn**
Reception follows in the Great Hall - all participants welcome

Friday, March 11: Digging Deeper: Key Issues for U.S. Policy Choices

8:30 am **Registration**
(coffee and tea will be served)

9:00 **Informing Policy Design: Insights from the Science of Safety and the Science of Public Consultation**
Moderator: Baruch Fischhoff, Symposium Planning Committee Member

Discussants
Ruthanne Huising, McGill University
Gavin Huntley-Fenner, Huntley-Fenner Advisors
Monica Schoch-Spana, UPMC Center for Health Security

Open Discussion

10:30 **Break**

11:00 **Best Practices to Inform National Policy Design and Implementation: Perspectives of Key Stakeholders in the Biomedical and Public Health Communities**
Moderator: Philip Dormitzer, Symposium Planning Committee Member

Discussants
Michael Callahan, Massachusetts General Hospital and Harvard Medical School
Robert Fisher, U.S. Food and Drug Administration
Jonathan Moreno, University of Pennsylvania
Ethan Settembre, Seqirus

Open Discussion

12:30 pm **Lunch**
(seating available in the West Court and Members Room - follow signs)

1:30 **International Governance: Opportunities for Harmonizing GOF Research Policy and Practice**
Moderator: Ronald Atlas, Symposium Planning Committee Member

Discussants
Nisreen AL-Hmoud, Royal Scientific Society of Jordan
George F. Gao, Chinese Academy of Sciences and China CDC
Gabriel Leung, University of Hong Kong
Michael Selgelid, Monash University
Herawati Sudoyo, Indonesian Academy of Sciences and Eijkman Institute for Molecular Biology[1]

Open Discussion

3:00 **Break**

3:30 **Summing Up**
Moderator: Harvey Fineberg, Symposium Planning Committee Chair

Summary Remarks
Brief remarks from the moderators of the plenary sessions to summarize what emerged from the discussions during the symposium to inform the NSABB's recommendations and the U.S. government's policy choices.

Open Discussion

Concluding Remarks
Harvey Fineberg, Symposium Planning Committee Chair

5:00 **Adjourn**

[1] Dr. Sudoyo was unable to take part in the symposium

Appendix D

Speaker and Panelist Biographies

Nisreen AL-Hmoud obtained a Ph.D. in microbiology from Abertay University, Dundee, Scotland in 2002. In 2003, she joined the Royal Scientific Society (RSS) of Jordan as a researcher, and since 2009, she has been leading the group of Biosafety at RSS. Dr. AL-Hmoud is a member of the National Biosafety Committee and the National Committee for Science and Technology Ethics in Jordan. She also served as president of the Biosafety and Biosecurity International Consortium (BBIC) steering committee between May 2010 and July 2012. In October 2015, Dr. AL-Hmoud was appointed as director of the Centre for Excellence in Biosafety, Biosecurity and Biotechnology at RSS. Dr. AL-Hmoud started her teaching career in October 2006 as a visiting lecturer of medical microbiology at the department of Biology, Faculty of Science, at the University of Jordan. In February 2008, she joined Princess Sumaya University for Technology (PSUT) as an assistant professor, and later on as a department head and coordinator for the master's program of Environmental Technology and Management. She is also a lecturer at the Health and Community Development Program of Jordan and the School for International Training Study Abroad Program.

Michael Callahan is a physical scientist boarded in both internal medicine and infectious diseases and is a Diplomat of Mass Casualty Care and Tropical Medicine and Hygiene (UK). Dr. Callahan received his M.S. in International Public Health and his M.D. from the University of Alabama School of Medicine, where he was the 19th Tinsley Harrison Scholar

and received three academic and research awards in his graduate and medical training. His biodefense clinical research is focused on vaccine defeat, immune evade and multidrug-resistant organisms, and on best practices for highly dangerous pathogen infections in Africa where he prospectively enrolls cutaneous anthrax in Nigeria; and monkey pox, Ebola and Marburg in the Democratic Republic of the Congo and Angola. In 2002, he was appointed clinical director for Cooperative Threat Reduction programs at six former Soviet Union (ex) Biological Weapons Institutes (VECTOR, State Research Center for Applied Microbiology, Kirov, Bersk, RCMDT, Highly Pure, and RIHOP), which included redirecting of unanticipated dual use and gain-of-function programs. From 2005 to 2012, Dr. Callahan led the Defense Advanced Research Projects Agency (DARPA) biodefense therapeutics portfolio, which he expanded from $61 million to $260 million per annum in 2011, involving eight programs that generated nine investigational new drugs (INDs) and three new drug applications with products in market. While at DARPA he launched the Department of Defense Icon program Accelerated Manufacture of Pharmaceuticals (AMP), for which he received the 2010 DARPA Achievement Award, and which generated emergency use good manufacturing practice pH1N1 vaccines, and Nicotinia-expressed monoclonals such as ZMapp. Also while at DARPA, he launched Prophecy, the international physician Early Alert network, which delivers 24/7 emergency consultation, reagents and therapeutics for catastrophic (mass-casualty or HDP) infectious disease outbreaks, severe acute respiratory syndrome Hong Kong and H7N9 Nanjing. His drugs in market include Ambisome (Gilead), which has generated $6 billion since approval, cPG100, and four private-sector INDs involving novel anti-infectives, cytotherapeutics, or host-based antivirals. Dr. Callahan is president of United Therapeutics (UTHR) Division of Cell Therapeutics, and maintains faculty appointments at Massachusetts General Hospital/Harvard Medical School and King Chulalongkom Medical University in Bangkok. Dr. Callahan continues his federal service as infectious disease and biosafety SME to the Academies, the National Security Council, BSEG, the Office of Net Assessment, National Institute of Allergy and Infectious Diseases, MITRE, American Society of Microbiology, Infectious Disease Society of America, and the American Society of Tropical Medicine and Hygiene.

Rocco Casagrande is the Managing Director of Gryphon Scientific, LLC. His projects at Gryphon Scientific focus on bringing rigorous scientific analysis to problems of homeland defense. For the past dozen years, Dr. Casagrande has led more than 50 projects to evaluate and improve U.S. preparedness efforts for a chemical, biological, radiological, and nuclear attack or emerging infectious disease event and to support a

better understanding of the threat. Dr. Casagrande also served as the principal investigator of several projects supporting the U.S. government's stance on emerging biotechnologies, including the guidance to the synthetic DNA industry and its moratorium on funding research involving engineered influenza viruses. From December 2002 to March 2003, Dr. Casagrande served as an United Nations Monitoring, Verification and Inspection Commission (UNMOVIC) biological weapons inspector in Iraq where he acted as the chief of the United Nations biological analysis laboratory. Prior to working for UNMOVIC, Dr. Casagrande worked in private industry as an inventor in a nano/biotechnology company. Dr. Casagrande holds a B.A. in chemistry and biology from Cornell University, where he graduated magna cum laude, and a Ph.D. in biology from the Massachusetts Institute of Technology.

Ralph J. Cicerone is the president of the National Academy of Sciences. His research in atmospheric chemistry, climate change, and energy has involved him in shaping science and environmental policy at the highest levels nationally and internationally. Dr. Cicerone was educated at the Massachusetts Institute of Technology (B.S. in electrical engineering) and the University of Illinois at Champaign-Urbana (M.S., Ph.D. in electrical engineering, with a minor in physics). In his early career, he was a research scientist and held faculty positions in electrical and computer engineering at the University of Michigan. The Ralph J. Cicerone Distinguished University Professorship of Atmospheric Science was established there in his honor in 2007. In 1978, he joined the Scripps Institution of Oceanography at the University of California, San Diego, as a research chemist. From 1980 to 1989, he was a senior scientist and director of the Atmospheric Chemistry Division at the National Center for Atmospheric Research in Boulder, Colorado. In 1989, he joined the University of California, Irvine, where he was founding chair of the Department of Earth System Science and was appointed the Daniel G. Aldrich Professor of Earth System Science. As dean of the School of Physical Sciences from 1994 to 1998, he recruited outstanding faculty and strengthened the school's curriculum and outreach programs. Immediately prior to his election as Academy president, Dr. Cicerone served as Chancellor of University of California, Irvine, from 1998 to 2005, a period marked by a rapid rise in the academic capabilities of the campus. His research has focused on atmospheric chemistry, the radiative forcing of climate change due to trace gases, and the sources of atmospheric methane, nitrous oxide, and methyl halide gases.

Louis "Tony" Cox is president of Cox Associates, a Denver-based applied research company specializing in quantitative health risk analysis, casual modeling, advanced analytics, and operations research. Since 1986, Cox

Associates' mathematicians and scientists have applied computer simulation, biomathematical models, biostatistical and epidemiological risk analyses, casual data mining, machine learning, biomathematical modeling and bioinformatics, operations research, and artificial intelligence models to measurably improve health and engineering risk assessment and decision making for public and private sector clients. In 2006, Cox Associates was inducted into the Edelman Academy of the Institute for Operations Research and Management Science (INFORMS), recognizing outstanding real-world achievements in the practice of operations research and the management sciences. In 2012, Dr. Cox was inducted into the National Academy of Engineering (NAE) "for applications of operations research and risk analysis to significant national problems." He is a member of the Academies Board on Mathematical Sciences and their Applications (BMSA) and a member of the Academies Standing Committee on the Use of Public Health Data in Food Safety and Inspection Service Food Safety Programs. Dr. Cox holds a Ph.D. in Risk Analysis (1986) and an S.M. in Operations Research (1985), both from the Massachusetts Institute of Technology; an A.B. from Harvard University (1978); and is a graduate of the Stanford Executive Program (1993). He is honorary full professor of Mathematics at the University of Colorado, Denver, where he has lectured on risk analysis, biomathematics, health risk modeling, computational statistics and causality; is on the Faculties of the Center for Computational Mathematics and the Center for Computational Biology; and is clinical professor of Biostatistics and Informatics at the University of Colorado Health Sciences Center. Dr. Cox is editor-in-chief of *Risk Analysis: An International Journal*, is area editor for Real World Application for the *Journal of Heuristics*, and is on the Editorial Board of the *International Journal of Operations Research and Information Systems*. He is an Edelman Laureate of INFORMS, a member of the American Statistical Association (ASA), and a fellow of the Society for Risk Analysis (SRA).

Ruxandra Draghia-Akli joined DG Research and Innovation of the European Commission as health director in 2009. In her position, Dr. Draghia-Akli is constantly seeking to deepen the reach, the breadth, and the depth of Europe's excellence in health research and innovation (R&I). Before joining the European Commission, Dr. Draghia-Akli served as vice president of Research at VGX Pharmaceuticals (now Inovio) and VGX Animal Health. She received an M.D. from Carol Davilla Medical School and a Ph.D. in human genetics from the Romanian Academy of Medical Sciences. She also completed a doctoral fellowship at the University of Rene Descartes in Paris and post-doctoral training at Baylor College of Medicine and served as faculty at Baylor. In 2012, she became an honorary member of the Romanian Academy of Medical Sciences.

Gerald Epstein is a fellow of the American Physical Society and the American Association for the Advancement of Science. He serves on the editorial board for the journal *Biosecurity and Bioterrorism* and has served on the Biological Threats Panel of the National Academy of Sciences' Committee on International Security and Arms Control and the Biological Sciences Experts Group for the Office of the Director of National Intelligence. He also served on the Committee on Science, Security, and Prosperity, which produced the report *Beyond Fortress America: National Security Controls on Science and Technology in a Globalized World*. He received B.S. degrees in physics and electrical engineering from the Massachusetts Institute of Technology and a Ph.D. in physics from the University of California, Berkeley.

Adam Finkel is currently executive director of the Penn Program on Regulation at the University of Pennsylvania, where he is also a senior fellow at the Penn Law School, and is clinical professor of Environmental Health Sciences at the University of Michigan School of Public Health. From 2004 to 2007, he was a visiting professor of Public and International Affairs at the Woodrow Wilson School at Princeton University. From 2000 to 2003, Dr. Finkel was regional administrator for the U.S. Occupational Safety and Health Administration (OSHA) in Denver, Colorado, responsible for regulatory enforcement, compliance assistance, and outreach activities in the six-state Rocky Mountain region (Region VIII). From 1995 to 2000, he was Director of Health Standards Programs at OSHA headquarters, and was responsible for promulgating and evaluating regulations to protect the nation's workers from chemical, radiological, and biological hazards. Dr. Finkel holds an Sc.D. in environmental health sciences from the Harvard School of Public Health, an M.A. in public policy from Harvard's John F. Kennedy School of Government, an A.B. in biology from Harvard College, and is a certified industrial hygienist. Dr. Finkel has pioneered methodological improvements in human health risk assessment and cost–benefit analysis for the past 25 years, primarily in the areas of quantitative uncertainty analysis, accounting for interindividual variability in susceptibility, and designing regulatory processes to maximize stakeholder input and shed light on economic impacts. He is co-author of four books, including the 2014 volume *Does Regulation Kill Jobs?* In 2006, he received the David P. Rall Award for Advocacy in Public Health from the American Public Health Association for "a career in advancing science in the service of public health protection." In 2013, he received the Alumni Leadership in Public Health Practice Award from the Harvard School of Public Health.

Robert Fisher is director, Regulatory Science for the Food and Drug Administration's (FDA's) Office of Counterterrorism and Emerging

Threats (OCET) and the Medical Countermeasures Initiative (MCMi). He leads the MCMi Regulatory Science Program, oversees intra- and extramural research programs, and works with FDA Centers, PHEMCE stakeholders, and other U.S. and international partners on medical countermeasure-related regulatory science issues. Dr. Fisher joined FDA's Center for Biologics Research and Review (CBER) as a staff fellow in 2006, and served as a staff scientist from 2013-2015. During his tenure at CBER, he provided scientific leadership for regulatory review of chemical, biological, radiological, and nuclear (CBRN) medical countermeasures. He maintained an active research interest in several medical countermeasure related fields, including the modeling of complications related to vaccinia live-virus vaccines and investigating methods for improved characterization of botulism and anthrax antitoxin products. Dr. Fisher received his undergraduate degree in biology from the University of North Carolina at Pembroke and a Ph.D. in toxicology from the University of North Carolina at Chapel Hill. He studied filovirus and poxvirus pathogenesis under a National Research Council Research Associateship at the U.S. Army Medical Research Institute of Infectious Diseases and holds a certificate in Biohazardous Threat Agents and Emerging Infectious Diseases from Georgetown University.

Richard Frothingham is an associate professor of Medicine at Duke University Medical Center. He received his B.S. from the Massachusetts Institute of Technology and his M.D. from Duke. He completed clinical training programs in Medicine, Pediatrics, and Infectious Diseases and maintains board certification in Infectious Diseases. He is also a Certified Biological Safety Professional. Dr. Frothingham directs the National Institute of Allergy and Infectious Diseases Regional Biocontainment Laboratory at Duke University. This laboratory was built to support research to develop drugs, diagnostics, and vaccines for emerging infections and biological threats. The Frothingham lab studies host responses to tuberculosis with the goal of developing better vaccines and treatments. Dr. Frothingham also provides clinical care to persons with HIV infection. Dr. Frothingham serves as co-chair of the Duke Institutional Biosafety Committee (IBC). The Duke IBC has reviewed and managed biological research with the potential for dual use since 2005.

Keiji Fukuda is special representative for antimicrobial resistance for the director-general at the World Health Organization (WHO). He previously served as the assistant director-general for health security, the special adviser on pandemic influenza to the director-general, and director of the Global Influenza Programme. Before joining WHO, Dr. Fukuda served as the chief of the Epidemiology Unit, Influenza Branch, Centers for Disease

Control and Prevention (CDC) in the United States. He has extensive global and national public health experience with health security and emerging infectious diseases, including field investigations and research, capacity building and preparedness, communications, surveillance, and with international governance and frameworks such as the International Health Regulations, the Pandemic Influenza Preparedness Framework and the Codex Alimentarius. He is currently focusing on shaping the global approach to antimicrobial resistance. Dr. Fukuda is a physician and epidemiologist and received his B.A. from Oberlin College, his M.D. from the University of Vermont, his M.P.H. from the University of California, Berkeley, and additional training in epidemiology at CDC.

George Gao obtained his Ph.D. (D.Phil.) degree in 1995 from Oxford University, United Kingdom. He was selected by the Chinese Academy of Sciences "Hundred Talents" program in 2004, and received the National Natural Science Foundation of China (NSFC) Distinguished Young Scholar title in 2005. He is the chief scientist of two consecutive projects on the mechanism of interspecies transmission of viral pathogens and a leading principal investigator of the NSFC Innovative Research Group. He is also a member of the steering committee for the International Consortium of Anti-Virals (ICAV), and a visiting professor at Oxford University. He was awarded the World Academy of Sciences (TWAS) prize in Medical Sciences in 2012 and the Nikkei Asia Prize in 2014. Dr. Gao is a member of the Chinese Academy of Sciences, a fellow of TWAS, a fellow of the American Academy of Microbiology, and the director and professor in the Chinese Academy of Sciences Key Laboratory of Pathogenic Microbiology and Immunology, Institute of Microbiology. He is also the vice president of the Beijing Institutes of Life Science, Chinese Academy of Sciences, Deputy Director-General of the Chinese Center for Disease Control and Prevention, and dean of the UCAS Cunji College of Medicine.

Margaret Hamburg earned her B.A. from Harvard College, her M.D. from Harvard Medical School, and completed her residency at what is now New York Presbyterian Hospital-Weill Cornell Medical Center. She conducted neuroscience research at Rockefeller University in New York and at the National Institute of Mental Health, and later focused on HIV/AIDS research and policy as assistant director of the National Institute of Allergy and Infectious Diseases. In 1991, after just 1 year in the New York City Department of Health, Dr. Hamburg was named its commissioner. During her 6-year tenure, she implemented rigorous public health initiatives that tackled the city's most pressing crises head-on—including improved services for women and children, a needle-exchange program to combat HIV transmission, and the nation's first public health bioterrorism

defense program. The most celebrated achievement during her leadership was her aggressive approach to the city's tuberculosis epidemic, which led to an 86 percent decline in drug-resistant tuberculosis in just 5 years. In 1997, 3 years after she was elected one of the youngest-ever members of the Institute of Medicine, President Bill Clinton named Dr. Hamburg assistant secretary for planning and evaluation in the Department of Health and Human Services, where she served until the end of the Clinton Administration. She then became founding vice president for biological programs at the Nuclear Threat Initiative, a foundation dedicated to reducing the threat to public safety from nuclear, chemical, and biological weapons. President Barack Obama nominated Dr. Hamburg for the post of the Food and Drug Administration commissioner on March 14, 2009. Dr. Hamburg is a member of the National Academy of Medicine and currently serves as its foreign secretary.

Jo Handelsman is the associate director for science at the White House Office of Science and Technology Policy (OSTP), appointed by President Obama and confirmed by the Senate in June of 2014. Dr. Handelsman helps to advise President Obama on the implications of science for the nation, ways in which science can inform U.S. policy, and on federal efforts in support of scientific research. Prior to joining OSTP, Dr. Handelsman was the Howard Hughes Medical Institute Professor and Frederick Phineas Rose Professor in the Department of Molecular, Cellular and Developmental Biology at Yale University. She previously served on the University of Wisconsin, Madison, faculty as a professor in plant pathology from 1985 to 2009 and as professor and chair of the Department of Bacteriology from 2007 to 2009. In 2013, she served as president of the American Society for Microbiology. Dr. Handelsman is an expert in communication among bacteria that associate with soil, plants, and insects and helped pioneer the field of metagenomics, bridging agricultural and medical sciences. Dr. Handelsman is also recognized for her research on science education and women and minorities in science, and received the Presidential Award for Excellence in Science Mentoring in 2011. Dr. Handelsman also co-chaired the PCAST working group that developed the 2012 report, "Engage to Excel," which contained recommendations to the president to strengthen STEM (science, technology, engineering, and mathematics) education to meet the workforce needs of the next decade in the United States. Dr. Handelsman received a B.S. from Cornell University and a Ph.D. in Molecular Biology from the University of Wisconsin, Madison.

Ruthanne Huising is an ethnographer of work and organizations. She studies how organizations respond to external pressures to change and the implications of these changes for professional control and expertise.

Across various projects she has observed how organizations accommodate regulatory change (Canada's Human Pathogens and Toxins Act), auditing fads (Environment, Health & Safety Management Systems), and efficiency efforts (Ontario's perioperative coaching program), and the complex responses of scientists, biosafety officers, health physicists, surgeons, nurses, and administrators. Ruthanne is an associate professor in the faculty of management at McGill University. She received her Ph.D. from the Sloan School of Management at the Massachusetts Institute of Technology.

Gavin Huntley-Fenner is an independent human factors consultant. His consulting and research interests are focused on the contribution of risk perception and reasoning to warnings effectiveness. Prior to focusing full-time as a human factors consultant, Dr. Huntley-Fenner was a business consultant at McKinsey & Company. He began his professional career as an assistant professor at the University of California, Irvine, after earning his Ph.D. in Brain and Cognitive Sciences from the Massachusetts Institute of Technology. From 2010-2014, he served as a member of the Food and Drug Administration's Risk Communication Advisory Committee.

Lawrence Kerr is the director of pandemics and emerging threats within the Office of Global Affairs at the Department of Health and Human Services (HHS). Dr. Kerr leads and manages the office, overseeing a broad policy portfolio including the global health security agenda implementation, pandemics and emerging threats, antimicrobial resistance, security policy issues (biosafety and biosecurity, biothreat prevention [Biological Weapons and Toxins Convention, United Nations Security Council 1540, Global Partnership against the Spread of Materials and Weapons of Mass Destruction]), and dual use research of concern. Prior to joining HHS in December 2015, Dr. Kerr served as the director for medical preparedness policy in the Resilience Directorate at the White House National Security Council Staff as the principal staff member responsible for coordinating policy regarding public health and medical resilience for biological events, whether the results of naturally emerging disease or deliberate release including his role on the Ebola Task Force. He previously served as the senior bio advisor to the director of the National Counterproliferation Center (NCPC) within the Office of the Director of National Intelligence. Dr. Kerr advised the senior leadership on strategic plans to prevent and counter the spread of biological weapons of mass destruction. Before joining NCPC in April 2006, he was director for biodefense policy with the White House Homeland Security Council in the Executive Office of the President. He served as assistant director for homeland security for the Office of Science and Technology Policy (OSTP) and as director

of bioterrorism, research and development for the Office of Homeland Security in the Executive Office of the President. Dr. Kerr joined the Life Sciences division of OSTP in January 2001, where he came from his position at the National Institute of Allergy and Infectious Diseases at the National Institutes of Health. He holds a B.S. in Biology and Art History and a Ph.D. in Cell Biology, both from Vanderbilt University.

Gabriel Leung is dean of medicine and chair professor of public health medicine at The University of Hong Kong. Previously he was Hong Kong's first under secretary for food and health, then director of the chief executive's office in government. Dr. Leung is one of Asia's leading epidemiologists, having authored more than 400 scholarly papers and edited numerous leading journals. He directs the university's World Health Organization Collaborating Centre for Infectious Disease Epidemiology and Control. His research defined the epidemiology of two novel viral epidemics, namely severe acute respiratory syndrome coronavirus in 2003 and influenza A (H7N9) in 2013. While in government, he led Hong Kong's policy response against the 2009 influenza A (H1N1) pandemic.

Jonathan Moreno is 1 of 16 Penn Integrates Knowledge university professors at the University of Pennsylvania, holding the David and Lyn Silfen chair. He is also professor of medical ethics and health policy, of history and sociology of science, and of philosophy. Dr. Moreno is a senior fellow at the Center for American Progress in Washington, DC. In 2008-2009 he served as a member of President Obama's transition team. His work has been cited by Al Gore and was used in the development of the screenplay for *The Bourne Legacy*. His online neuroethics course drew more than 36,000 registrants in 2013. Dr. Moreno's writings have been translated into Chinese, German, Japanese, and Portugese. The *American Journal of Bioethics* has called him "the quietly most interesting bioethicist of our time." Dr. Moreno is an elected member of the National Academy of Medicine. He has served as a senior staff member for three presidential advisory commissions, including the current bioethics commission under President Obama, and has given invited testimony for both houses of Congress. Dr. Moreno is the U.S. member of the United Nations Educational, Scientific and Cultural Organization International Bioethics committee. Dr. Moreno received his Ph.D. in philosophy from Washington University in St. Louis, was an Andrew W. Mellon postdoctoral fellow, holds an honorary doctorate from Hofstra University, and is a recipient of the Benjamin Rush Medal from the College of William and Mary Law School and the Dr. Jean Mayer Award for Global Citizenship from Tufts University.

Kara Morgan has 16 years of experience in risk analysis and decision analysis. She earned her B.S. in Mathematics from Michigan State University, her M.S. in Environmental Science from Indiana University, and her Ph.D. in Engineering and Public Policy from Carnegie Mellon University. After earning her Ph.D., she worked for 4 years at Research Triangle Institute, supporting the Environmental Protection Agency with the use of data-based decision making methods. Then, she spent 10 years at the Food and Drug Administration, working to support the development and implementation of risk-based decision-making tools and to implement strategic program planning for improving the achievement of outcomes. She is currently a research leader at Battelle Memorial Institute in the Health and Analytics sector. In that role, she works with clients to improve their use of data to inform decision making, supports knowledge management tasks related to quality measures for health care improvement, and works with clients to assess the outcomes their programs are achieving. She is also an adjunct professor at the Ohio State University's Glenn College of Public Affairs, where she teaches courses on risk and decision analysis. Dr. Morgan's professional focus has been on developing tools and methods for supporting effective data-driven risk management decisions. Her areas of emphasis include performance measurement, strategic planning, program evaluations, knowledge management, risk and decision analysis, and application of these tools and methods to improve decision making and improve outcomes.

Philip Potter obtained his Ph.D. in molecular carcinogenesis at the Paterson Institute for Cancer Research in Manchester, United Kingdom, and moved to St. Jude Children's Research Hospital in Memphis, Tennessee, shortly thereafter. His laboratory has worked for many years on the modulation of the response of tumor cells to chemotherapy, using both small molecule and molecular approaches. The latter has principally involved the use of adenovirus to deliver agents, such as ribozymes and drug metabolizing enzymes to cells, both in vitro and in vivo. Consequently, he has expertise in the design and construction of viral vectors and their practical use in the laboratory. Dr. Potter has more than 11 years of experience serving on the St. Jude Institutional Biosafety Committee, including as vice chairman and chairman. He is currently the vice chair of the IBC, and the chairman of the dual use research of concern subcommittee for the institution.

Monica Schoch-Spana, a medical anthropologist, is a senior associate with the University of Pittsburgh Medical Center (UPMC) Center for Health Security and a faculty member with the School of Medicine at the University of Pittsburgh and the Department of Anthropology at Texas State University. Dr. Schoch-Spana is a leading social science researcher in

public health emergency preparedness. Her studies have been influential in debunking myths about mass behaviors in the context of bioterrorism and other health crises and in reframing the management of catastrophic health events to include social, ethical-moral, and governance dimensions. National advisory roles include serving on the Homeland Security Subcommittee of the Board of Scientific Counselors for the Environmental Protection Agency, the Resilient America Roundtable of the National Academy of Sciences, and the National Research Council Committee on Increasing National Resilience to Hazards and Disasters. Dr. Schoch-Spana has chaired national working groups to produce peer-reviewed, evidence-based consensus guidance for authorities on how to partner with citizens and civil society in relation to bioterrorism response, influenza pandemic planning, and nuclear incident preparedness, and she has organized three national meetings on how to strengthen community resilience to extreme health events. Her current research projects focus on local health department capacity for community engagement, communication dilemmas concerning medical countermeasures, and public participation in the development of policies for allocating scarce medical resources in a disaster. In 2003, Dr. Schoch-Spana helped establish the UPMC Center for Health Security. Prior to that, she worked at the Johns Hopkins University Center for Civilian Biodefense Strategies starting in 1998. She received her Ph.D. in cultural anthropology from Johns Hopkins University and a B.A. from Bryn Mawr College.

Ethan Settembre is vice president and head of research for Seqirus. He holds a Ph.D. in biochemistry from Cornell University and completed his postdoctoral training in Structural Virology at Harvard Medical School. He then joined Novartis Vaccines & Diagnostics in 2008 where he held several key positions in research developing vaccines against multiple viral targets, including influenza. Currently, he heads the Seqirus Research group focused on influenza vaccine development.

Michael Selgelid is director of the Centre for Human Bioethics, and the World Health Organization (WHO) Collaborating Centre for Bioethics therein, at Monash University in Melbourne, Australia. He is a member of the board of directors of the International Association of Bioethics and serves on the Ethics Review Board of Médecins Sans Frontières. His main research focus is public health ethics with emphasis on ethical issues associated with infectious disease. He edits a book series in Public Health Ethics Analysis for Springer and a book series in Practical Ethics and Public Policy for ANU Press. He is co-editor of *Monash Bioethics Review* and an associate editor of the *Journal of Medical Ethics*. Dr. Selgelid earned a B.S. in

Biomedical Engineering from Duke University, and a Ph.D. in Philosophy from University of California, San Diego.

Samuel L. Stanley, Jr. was appointed as the fifth president of Stony Brook University in May 2009. Since that time he has presided over a tremendous growth of the university, through the implementation of a faculty hiring program that has brought 200 net new faculty to Stony Brook, a 5-fold increase in endowed professorships, the largest number of applicants and most accomplished classes in the school's history, and record fundraising totals, including one of the largest gifts ever to a public university. Before becoming president of Stony Brook University, Dr. Stanley served as vice chancellor for research at Washington University in St. Louis, where he had a distinguished career as a biomedical researcher with a focus on host defense against emerging pathogens. Dr. Stanley currently serves as the chair of the National Science Advisory Board for Biosecurity (NSABB), is a member of the National Security Higher Education Advisory Board (NSHEAB), is the chair of Brookhaven Science Associates (BSA), which manages Brookhaven National Laboratory, is a member the board of directors of Cold Spring Harbor Laboratory, and is a member of the board of directors of the Research Foundation, State University of New York.

Volker ter Meulen qualified as an M.D. in 1960. He received his post-doctoral training in virology in the United States, at the Children's Hospital of Philadelphia. On returning to Germany in 1996, he specialized in pediatrics and was subsequently visiting scientist at the Wistar Institute for Anatomy and Biology in Philadelphia and at the Viral and Rickettsial Disease Laboratory in Berkeley, from 1969-1970. In 1975 he became a full professor and chairman of the Institute of Virology and Immunobiology at the University of Würzburg. He retired in 2002, having twice been elected dean of the faculty of medicine at Würzburg University. During his research career, Dr. ter Meulen worked on molecular and pathogenic aspects of viral infections in man and animals, in particular on infections of the central nervous system. Internationally, Dr. ter Meulen has served on a number of committees of organisations and scientific societies/unions in the area of virology and infectious diseases, covering a broad spectrum of important issues connected to human and animal pathogens. From 2003-2010, Dr. ter Meulen was president of the German Academy of Sciences Leopoldina. From 2007-2010, he was president of the European Academies Science Advisory Council (EASAC), the association of the National Science Academies of the European Union, which is the IAP associated regional network for Europe. He was elected IAP Co-Chair in February 2013.

Silja Vöneky is co-director of the Institute for Public Law and is a professor of public international law, comparative law, and ethics of law at the University of Freiburg (Germany). Her areas of focus include international law, international humanitarian law, international environmental law, the law of the sea, international protection of human rights, the relation of ethics and law, and especially questions on how to regulate existential risks (biosecurity law and democratic legitimacy.) Since 2001, Professor Vöneky has served as the legal adviser to the German Federal Foreign Office, German Federal Ministry of Research, German Federal Ministry of the Environment, and the Alfred Wegener Institute for Scientific Marine and Polar Research. Since 2012, she has been a member of the German Ethics Council, appointed on the proposal of the federal government, and was the head of the Working Group on Biosecurity of the German Ethics Council.

Carrie Wolinetz is associate director for science policy and director of the Office of Science Policy (OSP) at the National Institutes of Health (NIH). As leader of OSP, she advises the NIH director on science policy matters of significance to the agency, the research community, and the public on a wide range of issues, including human subjects protections, biosecurity, biosafety, genomic data sharing, regenerative medicine, the organization and management of NIH, and the outputs and values of NIH-funded research. Prior to joining NIH, Dr. Wolinetz worked on biomedical research policy issues as the deputy director for federal affairs at the Association of American Universities (AAU) and the director of scientific affairs and public relations at the Federation of American Societies for Experimental Biology (FASEB). She also served as the president of United for Medical Research, a leading NIH advocacy coalition. Outside of NIH, Dr. Wolinetz teaches as an adjunct assistant professor at Georgetown University in the School of Foreign Service's program on Science, Technology & International Affairs. She has a B.S. in animal science from Cornell University, and she received her Ph.D. in animal science from Pennsylvania State University, where her area of research was reproductive physiology.

Risk and Benefit Analysis of Gain of Function Research
Final Report—April 2016
GRYPHON SCIENTIFIC

Risk and Benefit Analysis of Gain of Function Research

This work was conducted under NIH Contract# HHSN263201500002C with Gryphon Scientific from March 20, 2015 to December 15, 2015. Revisions were made until April 2016.

Susan Apter was the NIH contracting officer and Kelly Fennington was her representative

Acknowledgements:

The project team would like to acknowledge the guidance and assistance given by the NIH Office of Science Policy, specifically: Kelly Fennington, Christopher Viggiani, Stuart Nightingale (contractor), Kevin Ramkissoon, Marina O'Reilly, and Rona Hirschberg (contractor). We would like to thank Allison Mistry (Gryphon Scientific) and Luba Katz (Abt Associates) for their critical read and editing of the document. We thank Justin Anderson for his patience with formatting the many drafts of this document.

Also, we thank Barbara Johnson for her guidance on biosafety procedures in containment laboratories and Gerald Epstein and Wendy Hall of the Department of Homeland Security for a critical review of Chapter 8.

TABLE OF CONTENTS

1 Executive Summary

The analysis described in this report provides information for the NSABB to make recommendations about a general conceptual approach to the evaluation of Gain of Function studies and for the US government to formulate policy regarding Gain of Function (GoF) research. In this document, the term GoF is used in the same manner as the Framework for Conducting Risk and Benefit Assessments of Gain of Function Research—the "Framework". By design, this study was broad in its scope, intentionally assessing all of the traits and pathogens mentioned in the Framework to determine where risk lies. The conclusions of the risk assessment identify the pathogens and the enhanced phenotypes that increase risk of a pandemic and those that do not increase this risk. Similarly, the benefit assessment determines which experiments (regardless of their risk) have important and unique benefits.

This project is divided along the three major tasks, each of which requires a distinct data collection and analysis approach: 1) a risk analysis (RA) of accidents and natural disasters, 2) a biosecurity RA, and 3) a benefit assessment. The RA of accidents and natural disasters (called the biosafety RA for simplicity) leveraged sophisticated quantitative modeling of the probability and consequences of various events that lead to an outbreak, the ongoing transmission of the outbreak in humans, and the termination of the outbreak by public health measures or natural forces. The biosecurity RA includes an analysis of data from the intelligence and law enforcement community on malicious actors and an assessment of the efficacy of security measures at preventing or mitigating a hostile act. The biosecurity RA is delivered in two parts because risks posed by malicious acts targeting laboratories that conduct GoF required a different analytical approach than the assessment of the risk generated by the misuse of published GoF research. The benefit assessment identifies the gaps in scientific knowledge, public health, and medicine that GoF experiments could address. Moreover, this assessment discusses scientific and non-scientific barriers to the realization of these benefits.

1.1 Biosafety Risk Assessment

The Biosafety Risk Assessment is an estimation of the increase in risk to human health of outbreaks caused by modified strains of the influenza viruses and the coronaviruses released in an accident or natural disaster. This RA uses the word "coronavirus" to mean the coronaviruses that cause SARS or MERS and not the coronaviruses that cause the common cold. In every case, the increase in risk compared to wild type strains was provided to determine if GoF experiments could create pathogens that are more likely to cause laboratory acquired infections, to create a local outbreak, or to cause a global outbreak of greater consequence than those strains that evolved via natural forces. Note that although this study identified several types of risky, theoretical GoF experiments, many of these experiments have not been described in the literature. For example, no examples of researchers endeavoring to determine if seasonal influenza viruses could be made more transmissible were found. Moreover, some GoF studies are performed in highly attenuated strains, so that even though the risk of an outbreak increases if these strains were modified, risk is increasing from a very low level toward the level posed by wild type strains.

The main conclusion of the Biosafety RA is that a strain of influenza virus that is as transmissible as newly emerged pandemic strains WHILE producing a disease with a case fatality rate of more than 0.5% would pose more of a risk of a global pandemic than any wild type strain heretofore identified. No experiments that are likely to be conducted under the rubric of GoF research will drive risk more than this combination of traits or significantly increase the risk of a laboratory acquired infection. All other combinations of traits would lead to pathogens that have a lesser total risk than the wild type 1957 H2N2 pandemic strain. Increasing the transmissibility of the coronaviruses, while significantly increasing the

risk of work with those pathogens, still creates a pathogen that poses less of a risk of a global pandemic than the wild type 1957 influenza strain.

Another major finding of this risk assessment is that only a small minority of loss of containment events, which are rare in themselves, lead to a global pandemic. Only 0.5% of laboratory associated infections of seasonal influenza would seed a global pandemic, even assuming the accident was with a strain that has not circulated recently. If the strain released is currently in circulation, the spread of the outbreak is likely to be driven by travelers, not by laboratory accidents. If the released strain circulated recently, residual immunity is likely to curtail its spread. Only 1% of laboratory associated infections with wild type pandemic influenza strains would seed a global pandemic. Wild type strains of avian influenza and the diseases caused by the coronaviruses are insufficiently transmissible to have a significant chance of causing a global pandemic.[1]

Because seasonal influenza viruses are associated with a low case fatality rate, GoF experiments that increase this rate could significantly increase the global death toll from an outbreak, increasing risk. Developing seasonal influenza strains that are more transmissible than wild type strains (approximately as transmissible as pandemic strains) or that overcome residual immunity increases the probability that an outbreak would escape local control and exacerbates the consequences should a global outbreak be initiated (in terms of both morbidity and mortality). The creation of an antiviral resistant strain could increase the consequences of a global outbreak, but only in more economically developed countries where caches of these antivirals could be administered to a significant fraction of the infected population. A strain of seasonal influenza that can overcome protective vaccination could also increase the consequences of an outbreak in high income countries, which has the resources to vaccinate their population quickly. However, this phenotype is of concern only if immune evasion is afforded by means other than changing its antigenic properties, which is not a subject of current research in influenza. An unresolved question (which likely depends on the biology of the virus released and its similarity to currently circulating strains) is if the laboratory-associated outbreak of seasonal influenza would replace the annual toll of seasonal influenza by supplanting circulating strains or if it would add to this toll.

If GoF strains of seasonal influenza were manipulated at the BSL-3 instead of the BSL-2 level, risk overall may not increase much compared to work on wild type strains at BSL-2. That is, the rate of laboratory acquired infections is likely to decrease by three-fold, whereas any GoF phenotype (except for large increases in pathogenicity) increases risk by slightly more than three-fold.

In contrast to the several GoF manipulations that could increase the risk posed by seasonal influenza strains, only two lines of GoF research could create a strain of pandemic influenza that poses more risk of a global outbreak than a wild type strain (in this case, the 1957 H2N2 pandemic strain). The first is the manipulation of a strain of 1918 H1N1 pandemic influenza that is modified to evade residual immunity (or otherwise increase transmissibility to the same as a strain with novel antigenic properties). The second is the enhancement of pathogenicity (to that of 1918 H1N1 influenza) of a highly transmissible pandemic strain (such as 1957 H2N2 influenza). Imbuing 1957 H1N1 influenza with antiviral resistance can modestly increase the consequences of an outbreak, but only in countries with significant caches of antivirals. Enhancing viral growth in culture beyond that which is achievable in wild type strains (1E9 or 1E10/ml) increases the probability that a laboratory acquired infection would occur (by five- or 15-fold, respectively). However, it is doubtful if this phenotype is desirable or scientifically achievable because growth to 1E8 is sufficient for almost all purposes except the production of vaccines (using attenuated strains).

---

[1] Althought the SARS outbreak spread to several locations on multiple continents, it was extinguished in all locations (each of which could be thought of as a new, local outbreak) and did not lead to millions of cases worldwide.

Wild type avian influenza is insufficiently transmissible amongst people to cause a global outbreak driven by the spread of the disease among humans. For this reason, no loss of containment event would lead to a global outbreak from a wild type strain. Because wild type strains of avian influenza cannot spread globally between people, the creation of strains that are human-transmissible would greatly increase the risk that such an outbreak could occur, which could cause millions of illnesses. The creation of a strain that is as transmissible as seasonal influenza would have a significant chance of sparking a global outbreak if a local outbreak were initiated. Assuming that the case fatality rates of the most pathogenic strains of avian influenza are inflated by the underreporting of mild illness in people, increasing the pathogenicity in humans could increase the consequences modestly. Adapting avian strains to humans without increasing transmissibility (thereby lowering the median infectious dose in people) actually decreases risk because while this manipulation increases in the probability that a single laboratory worker would become infected, it decreases the risk that birds would become infected through an accidental release via the solid waste stream, which could lead to thousands of human infections from contact with infected birds. No other GoF increases the risk posed by avian influenza.

Similarly, most estimates of the transmissibility of the coronaviruses consider these pathogens to be insufficiently transmissible and sufficiently susceptible to control measures such that a global pandemic has a very minimal chance of occurring. For this reason, increasing the transmissibility of the coronaviruses could significantly increase the chance of a global pandemic due to a laboratory accident. Because SARS-CoV is more transmissible than MERS-CoV, a relatively modest increase in transmissibility of SARS-CoV could increase risk, whereas MERS-CoV must be made significantly more transmissible to drive risk. That being said, even if these strains were modified to be as transmissible as pandemic influenza, the susceptibility to control measures of the outbreaks they cause would still contain a majority of the outbreaks initiated. Some researchers have posited that the transmissibility of wild type SARS-CoV is quite high. If they are correct, then increasing the transmissibility of SARS-CoV would not influence risk significantly because the risk of a global pandemic arising from an outbreak is already significant. Increasing the pathogenicity of these strains could also increase risk somewhat through the increase in global deaths expected, especially since most deaths from wild type strains are suffered by those with significant co-morbidities. However, if a coronavirus were modified such that it caused a global pandemic, their long incubation time and disease course[2] lead to a pandemic that unfolds over many years. The fact that the outbreak evolves slowly gives public health authorities more time to adapt and expand their efforts to further contain the outbreak than the modeling conducted in this assessment suggests. If a strain with enhanced growth properties was developed and samples with 1E9pfu/ml or 1E10pfu/ml were routinely manipulated in a laboratory, the risk of a laboratory acquired infection in a coronavirus laboratory would increase by up to ten-fold, respectively. However, it is uncertain if this phenotype is desirable or even achievable given that the wild type coronaviruses grow sufficiently well in culture.

The laboratory features and practices that most influence risk include the strict adherence to incident reporting and isolation protocols for laboratory workers. Minimizing the chance that a worker would violate either of these protocols can decrease the risk that an infected laboratory worker would create an outbreak by up to seven-fold when working with seasonal influenza virus or by ten-fold with the coronaviruses. Additionally, when working with the coronaviruses (which are more stable in the environment than the influenza viruses), protocols to minimize the hazard posed by the contamination of the hands (proper use of double-gloving and thorough hand-washing) can reduce the probability of an infection by nearly fifty-fold. The probability that workers themselves commit errors that generate the laboratory accident is more than one-hundred-fold greater than the probability that a mechanical failure leads to an accident. While this conclusion is self-evident, it underscores how extensive worker training

[2] As described in Chapter 4, although the incubation times of influenza virus and the coronaviruses overlap, the variance of the incubation time and disease course is much greater for the coronaviruses than for influenza.

prior to entry into a BSL-3 laboratory, the assignment of highly trained workers for critical safety tasks (such as the operation of autoclaves) and the identification and re-training of careless workers could all significantly improve safety.

The state of knowledge of the rates and consequences of human errors in life science laboratories is too poor to develop robust predictions of the absolute frequency with which laboratory accidents will lead to laboratory acquired infections. Using historical incidents (and lack thereof) as a guide, a rate (at the 90% confidence level) of a laboratory acquired infection every three to 8.5 years can be set across the 100 or so laboratories that study influenza and the coronaviruses in the US. Given that this study predicts that 0.4% of these infections would lead to a global pandemic (since most of these laboratories study seasonal influenza, and not pandemic influenza), work with wild type influenza viruses would lead a global pandemic once every 750-50,000 years. A significant risk of an outbreak would be caused only if the strain released in the accident were a seasonal influenza strain that has not recently circulated, however, this outbreak could lead to up to 4,000,000 deaths worldwide. It is uncertain if these deaths would supplement or supplant the yearly death toll from seasonal influenza. Conservatively, an infection with a pandemic influenza strain could be expected to lead to a global pandemic once every 560-13,000 years, causing up to 80,000,000 deaths if the strain used were as pathogenic as the 1918 pandemic strain (and as transmissible as the 1957 pandemic strain). Given that viruses were characterized much less than 100 years ago, it cannot be stated with certainty that these pathogens will be studied under similar containment conditions far enough into the future for an accident to be likely to occur even once. Avian influenza strains and coronavirus strains are insufficiently transmissible to cause a global pandemic.

If sufficient funding were available, GoF research could be conducted by up to approximately 40 research groups in the US because these groups have been performing, or have the capacity to perform, certain types of GOF experiments involving influenza, MERS, and SARS viruses. This maximum number is supported by the case studies examined which showed that a new discovery in virology may proliferate to as few as one and as many as 70 new groups around the world within 10-15 years.

1.2 Biosecurity Risk Assessment of Malicious Acts Targeting a GoF Laboratory

The purpose of this component of the biosecurity risk assessment is to provide NSABB with an assessment of the increased human health risk posed by a malicious act involving a GoF strain of the influenza- or coronaviruses compared to malicious acts involving wild type strains. The risk assessment involved five steps: 1) characterization of the threat, which includes an evaluation of historical incidents and malicious actor motivation and capability (the "offense"); 2) review of the current security policies and practices landscape that governs research with influenza, SARS-CoV, and MERS-CoV in the United States (the "defense"); 3) identification of plausible threats based on analysis of the "offense" and "defense"; 4) assessment of the potential for the plausible threats to cause infections in the local community or broader; and 5) comparison of possible pandemic consequences of plausible threats involving GoF viruses and non-GoF viruses. All of the data collected were used to assess the plausible threats facing laboratories that perform GoF research. These plausible threats serve as the most probable events that could lead to a loss of containment from a biosecurity incident. Therefore, they were used to focus the quantitative analysis of local and widespread infections on those acts that are the most plausible in today's laboratory security environment.

Based on historical incidents and an assessment of the security governance in the United States, the most likely malicious acts to be carried out in or on a containment laboratory include theft of virus stocks, experimental samples, equipment, or research animals; deliberate contamination of personal protective equipment or laboratory equipment of co-workers; deliberate compromise of the personal protective equipment or laboratory equipment of co-workers; and mixing of infected with uninfected samples or

animals outside proper containment. In addition, incidents involving bombs or active shooters may cause loss of containment if carried out inside or near the entrance of high containment laboratories in which GoF research is conducted.

In today's regulatory and security environment, the most plausible malicious acts taking place at high containment, research laboratories involves malicious insiders who have authorized access to the laboratories and virus(s) contained therein. Insiders may work alone or in coordination with an outside group. Their motivations range from emotional disturbances to ideological radicalization by domestic and transnational terrorist organizations. The likelihood that outsiders could gain access to a laboratory without insider assistance is low. Therefore, outsiders present a threat to the periphery of the research complex or building only, but not a significant threat to the high containment laboratory itself.

Only a handful of GoF traits significantly increase biosecurity risk after a malicious event targets a laboratory. For seasonal and pandemic influenza, the ability to overcome protective vaccination and antiviral resistance modestly increases risk by increasing the potential consequences in high income countries. There is no significant effect on risk if the global population is considered as a whole. For seasonal and pandemic influenza, increasing the transmissibility and ability to evade residual immunity significantly increases risk because outbreaks are more likely to occur, to escape local control, and will create more consequential global outbreaks. For avian influenza, increasing transmissibility greatly increases risk because this modification is required to spark a global outbreak of a disease by human-to-human contact, potentially infecting millions. Without this change, the hazard is restricted to those exposed to contaminated materials and infected birds, limiting the outbreak to thousands of cases at most. Increasing pathogenicity can modestly increase risk. Similarly, the wild type coronaviruses have a very small chance of sparking a global outbreak so increasing transmissibility greatly increases risk. Increasing pathogenicity can modestly increase risk.

When comparing the biosafety and biosecurity risks, a successful event that covertly infects the public (theft from an influenza laboratory of an infected animal, contaminated piece of equipment or viral stock) must occur once every 80-5,500 years for biosecurity event to have the same total risk as biosafety events. Given the frequency with which these malicious acts have occurred in the past, this analysis suggests that biosecurity considerations be given as much weight as biosafety issues.

1.3 Biosecurity Risk Assessment of GoF Information

The biosecurity RA of GoF information is based on the open-source literature covering desirable characteristics of biological agents and the scientific literature on GoF studies and non-GoF studies with significant dual-utility. The potential biosecurity information risk that could be generated by GoF information was assessed compared to what could be achieved through dual-use studies that do not rely on GoF research. It was then determined if the unique dual-use information resulting from GoF studies had already been published.

Little information risk remains from GoF research on the influenza viruses. Although the development of a highly-contagious, highly virulent strain of influenza presents significant biosecurity information risk, the methods to produce these strains have already been published and so no information risk remains. Moreover, the specific changes in the genome that lead to these traits have also been characterized and published, so an actor could reproduce the dual-use strains using reverse genetics. Similarly, information on how to develop strains of influenza viruses that grow well in culture/eggs or evade medical countermeasures or diagnostics has some dual-utility, but the methods to create these strains also have already been published. A modest information risk would be realized if researchers published methods to produce strains of influenza viruses that can produce more prolonged or chronic illness. Although this

manipulation is a possible enhancement of pathogenicity that can fall under the definition of GoF research, there is little scientific rationale to undertake these experiments. Hence, the possibility that this information risk will be realized is low. Another modest information risk inheres in the publication of methods to produce strains of influenza virus that are able to overcome protective vaccination even if the vaccine matches the serotype of the pathogen. Similar work has been published for other pathogens, but these pathogens have larger and more plastic genomes than the influenza viruses, so it is not known if similar manipulations could be successfully carried out in the influenza viruses.

Significant information risk would be realized by the publication of methods to create a highly transmissible SARS- or MERS-coronavirus that maintains its pathogenicity. Notably, without an animal model of transmissibility for these pathogens, this information risk is unlikely to be realized in the near future. A modest information risk inheres in methods to manipulate the genomic targets of a diagnostic assay for coronavirus infections without compromising the other desirable traits of the pathogen.

State actors (and the sub-state groups they sponsor) are currently the only groups with the resources, expertise, motivation, and time to leverage this dual-use information. These states could protect their own populace from a global pandemic by secretly stockpiling vaccines that are protective against their modified strain. For this reason, states would be more likely to produce modified influenza viruses than coronaviruses (because no vaccines exist for this type of agent) and would probably be uninterested in developing strains able to overcome any vaccine (as this strain would vitiate their comparative advantage). Sub-national malicious actors may obtain the capability to replicate some of the less complex GoF studies, but have so far not demonstrated any capacity to work with viral agents and little capacity for waging biological warfare in general. Highly skilled individuals trained in biology would be capable of replicating GoF studies, but are currently constrained greatly by a lack of material resources and time that are available typically only to well-funded companies and research institutions.

Finally, no information risks unique to GoF research were identified. Similar techniques to those used in GoF experiments could be leveraged for other pathogens that are not captured by the moratorium (and are therefore outside the initial GoF framework assessed in this document) to create a highly transmissible strain of an already deadly virus (like the Hendra and Nipah viruses) or to create a deadly strain of an already highly transmissible pathogen that has been modified to overcome protective vaccination (polio-, mumps- or measles-virus). Perhaps most worryingly, reverse genetics techniques could be used to synthesize smallpox virus if an actor has significant molecular biology skill, and this strain could be modified to overcome protective vaccination. Non-GoF pathogens could be used to produce effective, novel incapacitating agents by the modification of a highly contagious virus (polio-, mumps- or measles-virus) to overcome protective vaccination.

1.4 Benefit Assessment of GoF Research

The benefit assessment describes the potential benefits of GoF research involving influenza viruses and coronaviruses, relative to two different types of alternative approaches: alternative experimental approaches that can provide the same or similar information, and alternative scientific or technical innovations that may similarly benefit public health through completely different mechanisms. Notably, this assessment is limited to the evaluation of GoF experiments that have been published in the scientific literature.

Within the field of CoV research, GoF approaches in the following phenotypic categories were identified: enhanced pathogen production, altered host range, enhanced virulence, and evasion of therapeutics in development. GoF approaches that alter host range and enhance virulence uniquely enable the development of animal model systems that recapitulate human disease pathogenesis, which are critical for

establishing the safety and efficacy of candidate vaccines and therapeutics and for the study of disease pathogenesis mechanisms. GoF approaches that enhance virulence are also uniquely capable of demonstrating that live attenuated vaccines (LAVs) do not recover virulence upon growth *in vivo*, an important aspect of safety testing of candidate LAVs. Of note, this particular type of experiment simply increases the human health risk of the attenuated strain to approach that of wild type strains. GoF approaches that enhance virulence represent the most efficient and effective strategy for discovering novel virulence factors, which may be good targets for new therapeutics. However, several alternative strategies for the development of new therapeutics are being actively pursued and have also shown promise. GoF approaches that lead to evasion of therapeutics in development are critical for the development and regulatory approval of new therapeutics. Because these therapeutics are not yet widely available, no increase in human health risk is posed by resistant strains. GoF approaches that alter host range and enhance virulence provide unique benefits to study cross-species adaptation and pathogenicity, but alternative approaches may also be used. Of note, this adaptation to a new host typically attenuates virulence in the original host (in the case of SARS and MERS-CoV, humans).

Within the field of influenza research, GoF approaches in the following phenotypic categories were identified: enhanced pathogen production, mammalian adaptation and enhanced transmissibility, enhanced virulence, evasion of vaccines or therapeutics, and evasion of existing natural or induced immunity. Across all GoF phenotypes, GoF approaches provide unique benefits to the study of the mechanistic basis of the phenotype under study as well as the evolutionary mechanisms driving acquisition of that trait, though alternative approaches may also be used. Alternative approaches have stringent limitations for the study of mechanisms underlying mammalian transmissibility of animal influenza viruses, as animal flu viruses that efficiently transmit in humans do not exist in nature. GoF approaches that enhance virus production are uniquely critical for the current ability to produce sufficient and timely influenza vaccines for seasonal flu epidemics and flu pandemics and represent the only strategy for improving existing vaccine production capabilities in the near-term. Of note, GoF approaches used in vaccine production attenuate an otherwise pathogenic strain while enhancing its growth properties. GoF approaches that enhance the infectivity, transmissibility, and virulence of animal flu viruses inform pandemic risk assessments of circulating influenza viruses, which guide downstream decision-making about investments in pre-pandemic vaccine development and other pandemic preparedness initiatives. Specifically, GoF approaches are uniquely critical for strengthening the predictive value of molecular markers for mammalian adaptation, transmissibility, and virulence, which can be used to infer phenotype from sequence for the risk assessment. In general, molecular marker data moderately contribute to the overall risk associated with a particular virus. However, molecular marker data play an important role in rapid risk assessments when novel flu viruses first emerge in human populations due to the early availability of viral sequence data. These risk assessments facilitate more rapid initiation of response activities such as pre-pandemic vaccine development. Of note, realization of this benefit is subject to significant advancements in the state of knowledge about mechanisms underlying mammalian adaptation, transmissibility, and virulence, as well as improvements to global public health laboratory infrastructure. In addition, molecular marker data guide selection of viruses used as the basis of pre-pandemic vaccines. GoF approaches that enhance the infectivity and virulence of influenza viruses are also used to develop animal models that support the study of disease pathogenesis and medical countermeasure (MCM) development. GoF approaches that lead to evasion of therapeutics in development are critical for the development and regulatory approval of new therapeutics. Of note, the acquisition of resistance to novel classes of therapeutics is not expected to confer cross-resistance to existing antivirals (i.e., adamantanes or neuraminidase inhibitors). Thus, when these experiments involve drug candidates within new classes of therapeutics, which are not yet widely available, no increase in human health risk is posed by resistant strains. However, similar approaches using licensed therapeutics inform therapeutic recommendations for seasonal influenza infections and pandemic preparedness initiatives for high-risk animal influenza viruses, but phenotypic approaches for antiviral sensitivity testing are also used for these purposes. GoF approaches that lead to evasion of vaccines are uniquely

capable of determining whether viruses can acquire mutations to escape neutralization of candidate broad-spectrum or universal influenza vaccines, a critical aspect of testing the potential field efficacy of vaccines in development. Most of these experiments involve next-generation influenza vaccine candidates targeting epitopes other than the globular head domain of the hemagglutinin (HA) protein, the target of current influenza vaccines. Given that the globular head domain of HA is the immunodominant protein of influenza viruses and that these next-generation vaccines are not yet widely available, strains that can overcome the protection afforded by these vaccines are expected to pose a minimal increase in human health risk relative to wild type strains. GoF approaches that lead to evasion of existing natural or induced immunity have potential to improve the efficacy of seasonal influenza vaccines, but this benefit is subject to advancements in the state of knowledge about the mechanistic basis of antigenic drift as well as expansion of sequencing capabilities across public health laboratories involved in global influenza surveillance. Finally, GoF studies involving reassortment, which may lead to one or more phenotypic changes, are uniquely capable of providing information that can be used to prioritize community-level interventions aiming to prevent opportunities for co-infections that could lead to the generation of reassortant viruses with phenotypic properties of concern.

2 Overview and Purpose

The overarching purpose of conducting the risk/benefit analysis (RBA) is to provide information for the NSABB to make recommendations about a general conceptual approach to the evaluation of Gain of Function studies, and for the US government to formulate policy regarding Gain of Function (GoF) research. In this document, the term GoF is used in the same manner as the Framework for Conducting Risk and Benefit Assessments of Gain of Function Research—the "Framework".[3] By design, this study was broad in its scope, intentionally assessing all of the traits and pathogens mentioned in the Framework to determine where risk lies. The conclusions of the risk assessment should point to the pathogens and the enhanced phenotypes that would increase risk of a pandemic and those that do not increase this risk. Similarly, the benefit assessment determines which experiments (regardless of their risk) have important and unique benefits. That being said, this study was not so broad as to assess the risk posed by experiments that could create pandemic pathogens that do not all within the Framework. Specifically, as discussed in Chapter 8, other pathogens that lie outside the framework could be manipulated to cause a global outbreak. Also, other traits of the influenza viruses and coronaviruses could be manipulated that would alter their pandemic potential (such as their environmental stability, which could significantly increase their risk of causing a laboratory acquired infection, and the probability that patients could transmit the disease to others prior to the onset of symptoms).

The specific goals of this assessment is to provide evidence on how particular GoF experiments affect the following possibilities:

- That an outbreak caused by a laboratory accident may occur,
- That an outbreak caused by a laboratory accident may increase in severity or extent,
- That a hostile actor may misuse the materials or information generated,
- That future or ongoing disease outbreaks or attacks could be prevented or mitigated, and
- That the life-science research in general would be advanced.

2.1 Organization of the Project

This project is divided along the three major tasks, each of which requires a distinct data collection and analysis approach: 1) a risk analysis (RA) of accidents and natural disasters, 2) a biosecurity RA and 3) a benefit assessment. The RA of accidents and natural disasters (called the biosafety RA for simplicity) leveraged sophisticated quantitative modeling of the probability and consequences of various events that lead to an outbreak, the ongoing transmission of the outbreak in humans and the termination of the outbreak by public health measures or natural forces. The biosecurity RA requires an analysis of data from the intelligence and law enforcement community on malicious actors and an assessment of the efficacy of security measures at preventing or mitigating a hostile act. The biosecurity RA is delivered in two parts because risks posed by malicious acts targeting laboratories that conduct GoF required a different analytical approach than the assessment of the risk generated by the misuse of published GoF research. The benefit assessment requires an understanding of the gaps in scientific knowledge, public health and medicine that GoF experiments could address. Moreover, this assessment requires the identification of scientific and non-scientific barriers to the realization of these benefits.

---

[3] Framework for Conducting Risk and Benefit Assessment of Gain-of-Function Research: Recommendations of the National Advisory Board for Biosecurity. May 2015. http://osp.od.nih.gov/sites/default/files/resources/NSABB_Framework_for_Risk_and_Benefit_Assessments_of_GOF_Research-APPROVED.pdf

2.2 Time Horizon

The life sciences are advancing extremely rapidly such that techniques commonly use today were unheard of a few years ago, and the findings are being applied to more and more facets of life. Hence, the state of science decades from now is impossible to predict; to ground the work in real science, the RBA is constrained by a five year time horizon. This time horizon is necessary because the approach is data driven and the future state of research protocols is unknowable, especially how these changes will affect stocks of pathogen, containment measures, public health measures, and gaps in scientific knowledge, public health and medicine. New modes of scientific inquiry could obviate GoF research or open up new opportunities for its application. New laboratory techniques could greatly reduce the chance that an accident would occur or that any infections may happen. Of relevance to biosecurity, the malicious actors who may misuse the fruits of GoF research in the far future may have motives or capabilities much different from those of today's actors.

Specifically, all risks are considered in a five year time horizon. In contrast, the follow-on benefits of a scientific discovery that is produced in a five year time-frame will be considered even if these benefits are realized further into the future. This expanded time-horizon for benefits is necessary because basic science finds its application in the field years after its discovery and some regulatory processes require more than five years by themselves before products borne of a scientific discovery can be used.

2.3 Interpreting the Results of the RBA

In this study, GoF phenotypes are analyzed individually so that the NSABB can understand how any particular anticipated change would affect risk in isolation. In reality, many of the phenotypes considered by the framework are inextricably linked. For example, a component of transmissibility of seasonal influenza in human populations is the protection afforded by exposure to similar strains in the past. For this reason, the ability to overcome residual immunity influences transmissibility. Similarly, adaptation to a host is a necessary component of being transmissible in that host. A strain that is adapted to a host is likely to grow to a higher titer in cells derived from that host and produce a higher titer infection in a living host. High titer infections may often lead to a greater amount of viral shedding, and so these phenotypes are likely related to transmissibility.

The modeling completed enables a complete assessment of how any combination of parameter values that describe the pathogen and control measures influences risk, however, all possible combinations of these values and their influence on risk cannot be shown concisely in a report. Instead, static slices through this very complex risk space are taken and shown as two-dimensional figures in this report that explore the effect of changing one parameter while allowing all others to vary.

This study examines the risk should a GoF experiment lead to a pathogen with particular traits. In a quantitative framework, these traits must be described numerically (such as a specific increase in the reproductive number of the outbreak or the median infectious dose). However, quantitatively translating empirical studies of transmission in animals to epidemiological predictions for human populations is impossible. That is, increases in transmissibility in ferrets in isolators cannot be linked to a specific increase in the reproductive number for outbreaks in human populations. Therefore, it is unknown if the enhanced transmissibility observed in GoF experiments done to date would significantly change the risk of an outbreak. Only one component of the transmissibility of a virus in a human population is the biology of the virus and the host because humans may change their behavior to reduce the risk of contact during a particularly worrying outbreak. In fact, a recent study estimates that the ferret model of influenza

can be used to explain only 66% of the variation in transmissibility in humans observed across subtypes.[4] Instead, this RBA can simply determine how particular increases in transmissibility of a pathogen causing a human outbreak would influence risk. The feasibility of achieving any particular phenotype via GoF research is a question of science.

Lastly, this study uses the actuarial definition of risk (risk is the product of probability and consequences of a bad event). Wherever possible, this study clearly describes how aspects of GoF research influence risk by increasing the probability that an outbreak would occur and/or by increasing the consequences should it occur. In this way, readers can use this document to inform their calculations based on other possible definitions of risk (the probability that a bad event of any consequence occurs, for example).

3 Overall Methodology

This project is divided along three major tasks, each of which requires a distinct data collection and analysis approach: 1) a risk analysis (RA) of accidents and natural disasters, 2) a biosecurity RA, and 3) a benefit assessment. The RA of accidents and natural disasters (called the biosafety RA for simplicity) requires sophisticated quantitative modeling of the probability and consequences of various events that lead to an outbreak, the ongoing transmission of the outbreak in humans and the termination of the outbreak by public health measures or natural forces. The biosecurity RA, which considers acts that originate in a GoF laboratory and the misuse of the information generated by GoF research, requires an analysis of historical data on malicious actors and an assessment of the efficacy of security measures at preventing or mitigating a hostile act. The benefit assessment requires an understanding of the gaps in scientific knowledge, public health and medicine that GoF experiments could address. Moreover, this assessment requires the identification of scientific and non-scientific barriers to the realization of these benefits.

3.1 RA of Accidents and Natural Disasters

If this assessment is to inform a system for the evaluation of future research, the RA of accidents and natural disasters must provide risk information about research that has yet to be initiated in locations that have yet to be identified. This RA must also consider work with wild type pathogens that does not fall under the umbrella of GoF research. Unfortunately, the experiments to manipulate pathogens with pandemic potential (PPP), the resultant phenotypes, the biosafety features of the laboratory, and the environment around the laboratory all could significantly influence risk. To cover the entire landscape of experiments, phenotypes, containment measures, and environments, we took a parametric approach to risk modeling. That is, we determined how changing any attribute of the pathogen, experiment, laboratory, or environment would affect risk and then bound this assessment in science by assigning real examples to particular values. For example, we assessed how the transmissibility of an influenza virus affects risk of an outbreak from arbitrarily small values of transmissibility through arbitrarily large values. In this manner, we provide information on how transmissible an influenza virus must be in order for risk to increase significantly. We then compared this "break point" to the transmissibility of known influenza viruses to provide context on the feasibility of novel strains reaching this level of transmissibility. A similar approach was taken with all GoF phenotypes. Similarly, biocontainment aspects and features of the environment were explored for their influence on risk and we highlight those features or qualities of the environment that may significantly influence risk.

Using this approach, we considered biosafety risk by its component parts: the *probability* that an event would occur that would lead to an infection outside the laboratory, the *probability* that the infection would lead to an outbreak that seeds a global epidemic, and the *consequences* of the global epidemic.

The RA of accidents and natural disasters began with the accidents and natural disasters themselves. Of all the events that COULD lead to a loss of containment that could befall a laboratory, we chose to quantitatively model those that were either identified as high-risk in previous laboratory risk assessments, cited as frequent causes of accidents in laboratories in incident reports or those that are uniquely relevant to GoF studies. These events included high-probability, low-consequence events (like spills), low-probability, high-consequence events (like earthquakes), and "maximum reasonably foreseeable events". Events that are both low-probability and low-consequence were considered but not modeled further because they will, by definition, not contribute to risk.

Because of the routine use of Fault Tree Analysis (FTA) in a Probabilistic Risk Assessment (PRA) framework in the estimation of risks arising from accidents and natural disasters creating technological hazards (accidents and disasters striking nuclear power plants and the chemical supply chain, for example),[5] we applied a similar methodology here. In FTA, the probability that a specific hazard is generated via a series of connected failures is estimated. This analysis method is most commonly used to understand how systems can fail and to identify the best ways to reduce risk. To explore the uncertainty in parameter values and the variety of possible paths through a fault tree, we employed Monte Carlo simulations, in which repeated, random draws of possible paths and parameter values are sampled to obtain an aggregate realization of risk. For each incident (and for all incidents in aggregate) we obtained a probability that various types and sizes of releases occur. The PRA estimated how frequently each release occurs and how much pathogen (or how many infected animals or people) is released. Releases could occur via aerosol, via an infected worker or animal, or via a contaminated worker.

For each release type, a different modeling approach was used. For releases that create an aerosol, we used an atmospheric dispersion model to determine how many people or animals are exposed to what dose of pathogen. Dose-response models were used to determine how many people or animals become infected. For releases of contamination on the body or clothing of a laboratory worker, a stochastic, Markov chain model was developed to determine how many people (if any) or how many animals (if any) become contaminated after being touched by the initial contaminated worker. For events that caused the infection of a laboratory worker, we used a stochastic model to determine if the worker violates the various procedural and medical monitoring protocols to determine the probability of initiating an outbreak in the community. As discussed further below, animal escapes were found to drive risk by escaping containment features within the laboratory and infecting workers who can then leave the laboratory instead of the animal escaping the laboratory entirely.[6]

Once a person was infected outside of the laboratory, we modeled the nascent local outbreak using a branching process model, which captures the fact that small outbreaks can be extinguished by stochastic factors and also public health measures, some of which may be unique to the communities around the laboratories. Branching process models are stochastic models that calculate how many individuals every contagious person infects in each generation. In our model, the probability of infecting a certain number of new individuals is determined by the transmissibility of the pathogen (described by the parameter R) and the variation in transmissibility between individuals (described by the parameter k) and modified by public health control measures. We used this model to determine the probability that any given outbreak would extinguish or grow beyond local control, given the properties of the pathogen, starting conditions (how many of what type of people are infected), and control measures.

Once an outbreak escapes local control, it seeds outbreaks throughout the world. We modeled the illnesses and deaths that occur in each region of the world using the HHS-BARDA Interactive Influenza Model, an SEIR model that considers the effect of the young and the elderly in the ongoing spread of the disease given contact rates between workplace, school, and home populations. Although this study did not attempt to evaluate the efficacy of public health response measures in detail, these measures must be captured in our RA because some GoF phenotypes may vitiate some control measures more than others (for example, the ability to overcome protective vaccination) and lead to a change in relative risk.

---

[5] For example, see Vesely et al. Fault Tree Handbook (NUREG-0492), U.S. Nuclear Regulatory Commission, January 1981, http://pbadupws.nrc.gov/docs/ML1007/ML100780465.pdf and Center for Chemical Process Safety, Guidelines for Hazard Evaluation Procedures, April 2008.

[6] The biosecurity section (Chapter 7) discusses an event that involves malicious actors stealing infected animals from a laboratory. In this event, the malicious actor is assumed to be infected by carrying the infected animals, and the infection of this person drives subsequent outbreak risk.

For pathogens that are transmissible amongst birds only, if a bird is infected outside of the laboratory, we assumed that the outbreak escapes local control and that human health consequences are suffered based on the consequences of past avian influenza outbreaks. This simple approach was taken because not enough data is available to support more robust modeling of the interplay of wild birds, domestic birds and humans for outbreaks caused by entirely novel, avian-transmissible pathogens that cannot be transmitted amongst people. If an avian-origin strain is modified to be transmissible in mammals, it was modeled as any other human-transmissible pathogen, as described above.

If a global epidemic is not triggered, consequences were tallied from the number of people infected in the laboratory or in the smaller-scale outbreak in the locality. Comparing the risk posed by GoF research to the risk posed by unmodified pathogens provides an understanding of which specific GoF experiments may lead to a significant increase in biosafety risk.

Because the risk of a laboratory accident is proportional to the number of laboratory workers manipulating dangerous strains of pathogens, we also characterized the proliferation potential of GoF research in the US should the funding pause be lifted. We assessed the potential interest and capability to perform GoF research in the US by an analysis of the scientific literature. We also examined funding availability and the sufficiency of containment space to perform the work. Lastly, we identified three cases of scientific discoveries in virology and traced their proliferation over the following years to provide additional insight.

3.2 Biosecurity RA of Malicious Acts Targeting a Laboratory

In the risk assessment of malicious acts targeting a laboratory, also known as the semi-quantitative biosecurity assessment, we compared the motivations and capabilities of a variety of malicious actors to the defensive systems arrayed against them to prevent the malicious act. Should a malicious act lead to the loss of containment, its consequences were modeled in the same manner as in the biosafety RA above.

No unclassified information describing the threats to research laboratories that store or study GoF influenza, SARS, or MERS-CoV virus is available. Therefore, to identify the types of acts that may target a GoF laboratory, our approach involved examining historical incidents involving life science laboratories and hospitals, evaluating the motivations and capabilities of malicious actors, and determining if and how existing security measures affect the likelihood of success of a malicious act. Plausible threats facing laboratories that study or store GoF virus(s) were extrapolated from this assessment. From this assessment, we can compare quantitatively how a malicious act would have different consequences if a GoF laboratory was targeted instead of a laboratory studying only wild type pathogens.

To organize our biosecurity data collection effort, we developed a matrix of malicious actors, acts, and consequences. This matrix was reviewed by officials from the law enforcement and intelligence communities to ensure that we captured all plausible combinations that could threaten biosecurity. We then populated this matrix with data drawn from historical events that involved malicious acts in laboratories in the US or overseas. This historical analysis provides an evidence-based method to understand, in a qualitative way, the probability that an event would occur and the type of resources these malicious actors bring to bear when targeting a laboratory.

To assess the capabilities of preventing malicious acts, we investigated the literature on legal authorities and systems supporting biosecurity and analyzed these authorities and systems for gaps that could be exploited by malicious actors. We also interviewed biosecurity stakeholders at institutions performing relevant research to understand specific systems in place at these locations.

We then compared the data on the motives and capabilities of the malicious actors to the capabilities of systems preventing their access to develop a series of qualitative scenarios that represent the "highest risk" biosecurity events. The consequences of these events were modeled using the methodology laid out in the biosafety RA as described above.

3.3 Biosecurity RA of GoF Information

In this assessment, we identified those GoF studies that, if published, would provide useful information over what is already published in the scientific literature to a malicious actor seeking to create a biological weapon. To perform this assessment, we first determined what is possible for a malicious actor to achieve using unmodified agents so that we can identify how GoF pathogens could afford *additional* capabilities to an adversary. We then characterized the state of the science regarding the enhancement of all traits described in the NSABB GoF risk and benefit framework to understand to what degree methods already exist in the literature that speak to the creation of modified strains of influenza viruses and coronaviruses with phenotypes attractive to malicious actors. In this way, we identified GoF research that would provide uniquely valuable information to a malicious actor for misuse over the body of dual-use research that already exists. Also, we identified if dual-use information already in the literature requires a particularly challenging technical approach in order to ascertain if an information risk could be suffered via the publication of an easier experimental route to the same product. Lastly, we used open-source information to understand if this unpublished dual-use information is actually desired by various malicious actors and characterized the technical skill, sophistication, and resources required for those actors to leverage this information.

3.4 Benefit Assessment

The approach to the benefit assessment is founded on the concept that the benefits of scientific research derive from applications of new scientific information or products to gaps in knowledge, public health, medicine, and other societal issues. To that end, a multi-step process was used to identify the potential benefits of GoF research.

1. A foundation for the analysis was established by independently:
    a. characterizing the expected scientific information and products derived from GoF studies of potential concern involving influenza viruses and coronaviruses (Pathogens with Pandemic Potential, or "PPPs"), and

    b. identifying gaps in scientific knowledge about PPPs and gaps in public health and medical capabilities related to the prevention and control of PPP outbreaks.

2. The scientific information/products derived from GoF research were mapped ("crosswalked") to the gaps in scientific knowledge, public health, and medicine,

3. Alternate experimental approaches and/or other scientific or technical innovations ("alt-GoF" approaches) that could address the same gaps were identified,

4. The barriers to the realization of GoF and alt-GoF benefits were evaluated,

5. The unique benefits of GoF research were identified by comparatively analyzing the benefits afforded by GoF research versus alternative approaches, in light of the barriers to the realization of each approach,

6. The potential for the unique benefits of GoF research to be globalized was assessed, and

7. Benefits to the production of influenza vaccines were quantitatively evaluated.

This analysis of GoF benefits was guided by the benefits of GoF research and associated benefit critiques proposed by infectious disease researchers and other GoF stakeholders during public meetings about GoF research and through perspectives published in scientific journals. Each proposed benefit and benefit critique was examined in detail through interviews with stakeholders involved in conducting scientific research, including PPP researchers and non-PPP researchers, and stakeholders involved in translating research insights into public health practice and policy. Additionally, this list of proposed benefits and benefit critiques was expanded upon through further analysis of the scientific literature. Each proposed benefit was then validated – the "crosswalk" of proposed benefits to gaps – through examination and analysis of the scientific literature (for benefits to scientific knowledge) or through interviews with stakeholders in public health and MCM development who are directly involved in applying the data or agents generated through GoF research to public health practice and policy and MCM development/production. The validation analysis included an assessment of the relevance and validity of all benefit critiques previously identified. Importantly, this analysis leveraged the evaluation of public health systems to understand the process by which the immediate applications of GoF research ultimately reduce human morbidity and mortality caused by influenza viruses and coronaviruses. Taken together, this analysis resulted in the identification of GoF research outputs with validated applications to scientific knowledge, public health, and medicine as well as an understanding of their downstream benefits to the health of human populations.

Some alternative experimental approaches or other scientific/technical innovations (hereafter referred to as "alt-GoF" approaches) may pose less risk than GoF studies but yield the same or similar benefits. As GoF studies comprise a subset of all research activities involving PPPs, this analysis focused exclusively on those alt-GoF approaches capable of targeting the same gaps in scientific knowledge and public health as GoF approaches. The potential benefits of alt-GoF studies were identified through the same process as for GoF studies: a crosswalk of the research outputs of alt-GoF studies to gaps in scientific knowledge, public health, and medicine related to PPPs. Importantly, in addition to alternative experimental approaches, alt-GoF approaches also include those scientific and technical innovations that address the same public health gaps that GoF can address but through a completely different mechanism. To complement the analysis of the net risks associated with the conduct of GoF research relative to research involving wild type pathogens, the benefit assessment highlights those types of GoF studies that may provide *unique* benefits to scientific knowledge, public health, and medicine relative to alternative approaches.

One of the most challenging aspects of weighing the risks and benefits of GoF research is that there is a temporal mismatch between the risks and the benefits of the research – the risks are assumed at the time the research is conducted, while the benefits to public health and medicine *may* accrue in the future. To enable the comparison of risks and benefits, the benefit assessment provides data on the likelihood that the potential benefits of GoF research will be realized by describing the barriers to the realization of the benefits. Two types of barriers were explored: scientific barriers and non-scientific barriers. Scientific barriers arise from uncertainties in the state of the science and/or in the meaning of the scientific outcomes of GoF studies, which may influence the nature and limit the scope of the benefit. Scientific barriers were identified through analysis of the scientific literature and interviews with infectious disease researchers. Non-scientific barriers include other technical innovations and regulatory factors that are essential for translation of the research, as well as gaps or inefficiencies in downstream aspects of the public health process that may limit the ultimate impact of the research application on human health. To identify non-scientific barriers, the gap analysis of public health and medical capabilities related to the prevention and control of PPP outbreaks was leveraged. Finally, the type of resources needed to

overcome or circumvent each barrier was defined, including advancements in scientific knowledge, improvements to public health infrastructure, and other factors, which serves as a proxy for the likelihood and timing of the realization of the benefits.

Whether risks and benefits are equally distributed across populations is also an important consideration in any risk-benefit comparison. To inform NSABB's deliberations on this issue, the benefit assessment qualitatively assessed the globalization potential of the identified GoF benefits, through analysis of historical case studies examining the globalization of similar benefits and through review of relevant USG policies on resource and information sharing. Benefits related to the production of influenza vaccines are amenable to quantitative analysis. This analysis leveraged models developed for the biosafety RA above to parametrically explore how changes in the availability of influenza vaccines can mitigate morbidity or mortality during seasonal flu epidemics and flu pandemics.

4 Background Information on Influenza Viruses, the Coronaviruses and GoF Research

4.1 Influenza Viruses

Throughout this report, the terms pandemic, seasonal, and avian are used. Seasonal influenza viruses include the strains of the H1N1 and H3N2 subtypes that cause morbidity on an annual basis. Pandemic influenza viruses include the 1918 H1N1, 1957 H2N2, 1968 H3N2 and 2009 H1N1 strains, which spread rapidly at least partially because the population had very little immunity. The 2009 H1N1 strain continues to circulate seasonally since its emergence, and is properly classified as both a pandemic strain and a seasonal strain (also the morbidity and mortality caused by this strain is more similar to seasonal strains than any of the previous pandemic strains). Similarly, today's seasonal H1N1 strains are descendants of the 1918 H1N1 strain and the seasonal H3N2 strains are descendants of the 1968 strain, so the distinction between pandemic and seasonal strains is one of timing (today's novel pandemic strain is tomorrow's seasonal strain).

Avian influenza strains are strains of influenza that are transmissible only amongst animals other than humans, especially birds. If an avian strain is modified to become transmissible in humans, we still call this an avian strain because of the characteristics of its wild type parents. Generally, this report is concerned with the highly pathogenic strains of the H5 and H7 subtypes.

4.1.1 Biology of Influenza

4.1.1.1 Overview

Influenza is a single-stranded, negative-sense RNA virus of the *Orthomyxoviridae* family. There are three types of influenza viruses—A, B, and C—that have a common genetic ancestry, but distinct genetic characteristics. Influenza type A can infect a variety of animal hosts and is further divided into subgroups based on its surface proteins. Type B viruses have a more limited host range with limited variation; influenza C causes only mild symptoms in humans and does not contribute to outbreaks.[7]

4.1.1.2 Virus Structure

The influenza genome is divided into eight RNA segments that encode viral proteins essential to the functionality of the virus. Each is folded into a rod-shaped, double-helical ribonucleoprotein complex (RNP).

[7] Centers for Disease Control and Prevention. Types of Influenza Viruses. http://www.cdc.gov/flu/about/viruses/types.htm. Last Update 2014. Accessed May 2015.

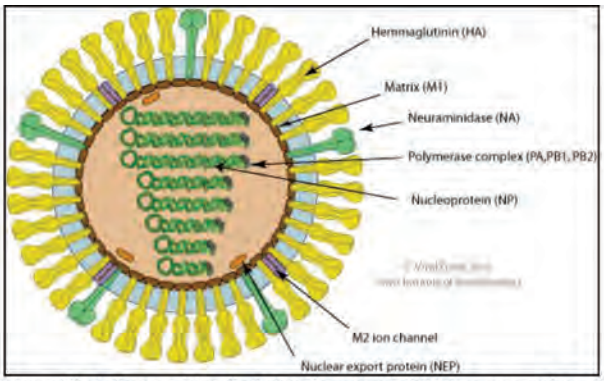

Figure 4.1. A cartoon of the influenza virion displaying the segmented RNA genome and encoded proteins, as reproduced from Le Mercier.[8]

The RNP contains viral RNA encapsulated by nucleoprotein (NP) and bound to a trimeric RNA polymerase, comprised of one polymerase acidic (PA) and two polymerase basic (PB1, PB2) subunits. The RNP is responsible for directing RNA replication, transcription, and transport as well as genome reassortment and packaging. Nuclear export proteins (NEP) also facilitate intracellular transport.

Matrix proteins, M1, surround the RNPs and NEPs. The lipid bilayer envelope encloses the virion with hemagglutinin (HA), neuraminidase (NA), and matrix ion channel (M2) proteins embedded into its membrane. HA glycoproteins facilitate virus binding and entry whereas NA proteins promote virus budding. HA recognizes the sialic acid moieties on host cells and ensure proper binding in preparation for endocytosis. NA proteins possess sialidase activity to release newly replicated virus from and prevent virus aggregation on the host cell. M2 ion channel proteins are vital for pH regulation during viral replication.[9,10,11]

4.1.1.3 Antigenic Variation

All influenza viruses are classified by type and strain. Influenza A viruses are also classified by their HA and NA subtype—e.g., H1N1, H3N2, H5N1. Influenza is a relatively simple RNA virus, yet is able to continuously elude host immune systems through antigenic drift. Influenza's RNA polymerase is prone to replication errors, resulting in frequent point mutations in antibody binding sites on HA and NA proteins. These amino acid changes have the potential to affect the conformation of surface proteins, and hence, the binding of host antibodies. Although these mutations are minor and random, accumulation over time can lead to a new strain of virus that is no longer neutralized by the host immune system, even after vaccination or prior infection.

Antigenic drift occurs in both influenza A and B. Influenza A viruses, however, can also evolve through a much more abrupt process referred to as antigenic shift, which is the result of genomic reassortment.

11 Tsai KN, Chen GW (2011) Influenza genome diversity and evolution. *Microbes Infect* 13: 479-488

The segmented feature of the virus genome enables the entire HA or NA segment to be replaced with a new segment from a different influenza virus. By altering the surface proteins, the infectivity of the virus is also altered and a new phenotypic subtype is formed. The HA protein is more likely to be reassorted, but both HA and NA subtypes have variable antigenicity.

Genomic reassortment occurs as a result of co-circulation of different subtypes of influenza A and co-infection of a host. When a host is infected with two influenza strains, viral replication in the nucleus may cause mixing of genetic material. Influenza is prone to genetic mixing due to its multiple-stranded genome (that is, a single newly budded virus particle could package RNA strands from two different parental strains). This mixing can result in a significant change of the antigenic properties of the virus, termed antigenic shift, and could generate a virus to which hosts have no existing immunity and, therefore, is the source of pandemic outbreaks. After a virus undergoes antigenic shift, it continues to experience antigenic drift. Both antigenic drift and antigenic shift are responsible for influenza's evolution and survival.[12,13]

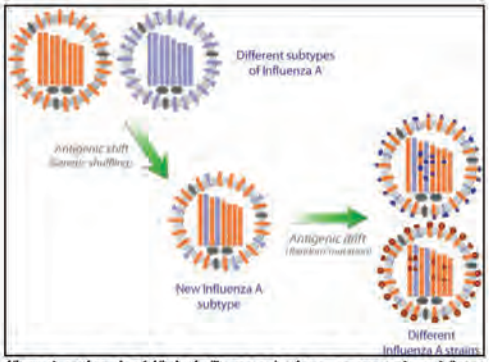

Figure 4.2. Antigenic drift and antigenic shift in influenza A virus, as reproduced from the WHO Collaborating Centre for Reference and Research on Influenza.[14]

4.1.1.4 Host Range

Influenza types, subtypes, and strains have a distinct and sometimes overlapping set of host organisms that they can effectively infect, called their host range or host tropism. For influenza viruses, sialic acid receptor specificity, temperature, and pH at the site of infection are the main determinants of host range.

Receptor specificity largely determines the host tropism of a virus. HA proteins bind to host glycosylated receptors with sialic acid moieties; different HA subtypes have preferences for different bond structures. HA in avian viruses binds only to the α-2,3 isoform whereas in human-adapted viruses, the α-2,6 linkage is preferred (Figure 4.3). Either HA type, however, will bind in swine because the species possesses cells with both sialic acid moieties. For this reason, swine are considered "mixing vessels" that provide an

opportunity for reassortment. Reassortment and evolution in intermediate hosts allow for emergence of new virus types. Figure 4.4 below shows the species adapted to different HA and NA subtypes.[15,16]

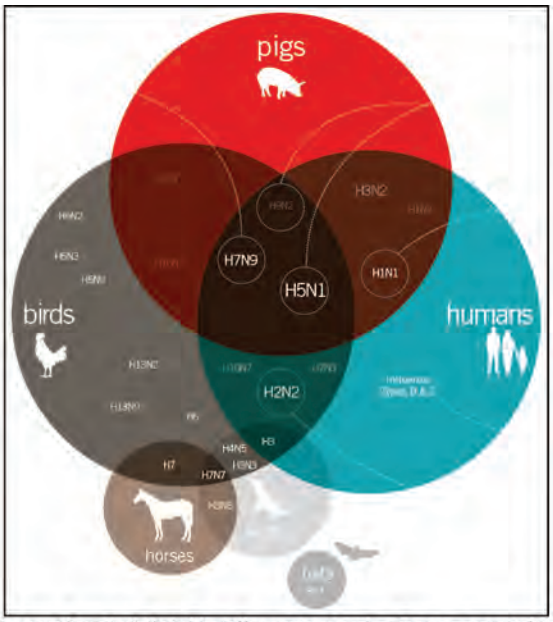

Figure 4.4. Venn diagram of species infected by influenza types and subtypes as reported by the CDC and WHO, adapted from McCandless et al. Size of text represents human fatality rates and lighter text shows the virus rarely infects humans.[18]

For effective transmission to another host, the virus must be able to efficiently replicate in the temperature of the new host and the site of infection in each host has a distinct temperature range. In birds, infection occurs in the gastrointestinal tract at around 40 degrees Celsius. In swine, influenza targets the respiratory tract at approximately 39 degrees Celsius. The upper respiratory tract in humans is typically around 33 degrees Celsius whereas the lower respiratory tract reaches 37 degrees Celsius. The lower respiratory tract also has α-2,3 moieties, which can be bound by avian strains. The elevated temperature, in combination with avian compatible viral receptors, presents the opportunity for a non-human-adapted virus to infect a human. Although rare, this is a source of unexpected species crossover, creating a variant influenza strain.[19,20]

HA glycoproteins facilitate viral infection of a host cell through pH-induced membrane fusion and some level of host tropism is determined by the pH of the infection site in various hosts. Change in pH may render the virus ineffective at transferring its genome into the host cell by causing the virus to release its genome at less proximity to the nucleus or once lysosomes have matured to degrade the genome. Either

will inhibit viral infection and replication. Viral adaption to a new host species requires a pH shift for effective membrane fusion.[21]

Currently only H1, H2, and H3 subtypes can easily cause human-to-human transmission. The emergence of a new subtype capable of human to human transmission is expected to cause a major pandemic because the population will have no pre-existing immunity.

4.1.2 Influenza Epidemiology[22]

Influenza is an acute viral infection characterized by the rapid onset of disease and brief symptomatic period. The virus can cause mild to severe respiratory illness in human hosts; some infections cause minor respiratory symptoms while others result in hospitalization and occasionally, death. Unresolved cases are usually associated with other chronic conditions and can develop into additional complications such as pneumonia and bronchitis.

4.1.2.1 Incubation Period

The incubation period is the time between when an individual is exposed to a pathogen and when the first symptom manifests. During the incubation period, most infected individuals cannot transmit the infection to others; therefore, longer incubation periods equate to a slower outbreak development. Incubation periods vary for seasonal, pandemic, and severe pandemic influenza.

4.1.2.1.1 Seasonal Influenza

Several papers were identified that describe the incubation periods observed in seasonal influenza infections. The literature suggests an incubation period duration ranging from one day to seven days (Supplemental Information Table 1). The most common incubation period found within the literature was two days with a mean incubation period of 63 hours or 2.6 days.[23,24,25,26,27,28,29]

4.1.2.1.2 Pandemic Influenza

Incubation periods for pandemic influenza are reported to be slightly longer than those seen in seasonal influenza. Since there is little to no data on the incubation period of other pandemic strains, data from the 2009 H1N1 outbreak were evaluated. Four sources from the 2009 H1N1 pandemic reported data on the length of incubation periods.

The H1N1 data suggest a range of incubation periods similar to the range seen in seasonal influenza.

However, these data suggest a mean incubation period of 4.2 days and median of 4.1 days instead of the two day incubation period most commonly seen in seasonal influenza.[30,31,32,33,34]

4.1.2.2 Infectious Period

The infectious period is the disease stage when an infected individual can transmit their disease to others. Currently, however, there is no definitive way to determine when an individual infected with influenza virus is contagious. The most widely accepted method of determining contagiousness is by measuring viral shedding. Under this method, an individual is deemed infectious when they begin shedding virus and stops being infectious when the viral shedding ends. The infectious period of seasonal and pandemic influenza is seemingly the same.

4.1.2.2.1 Seasonal and Pandemic Influenza

Data on when individuals infected with influenza stop shedding virus are extremely limited. The few availably papers typically assume that viral shedding begins at the onset of symptoms, and report only the average time after symptom onset when viral shedding ceases at 5.9 days.[35,36] Only Doyle et al. reported the distribution of viral shedding durations in addition to average duration.[37] In this study individuals were experimentally infected with influenza H1N1 virus (a pandemic strain) and monitored daily for viral shedding. All infected individuals shed virus for a minimum of three days after onset of symptoms, and a small percentage of individuals shed for eight or more days (see Supplemental Information on influenza disease course). However, more than 50% of those infected shed virus for six or seven days. The study also provided evidence that viral shedding occurred before symptoms were displayed, which would increase the total time of shedding. No other sources were available on the duration of viral shedding for influenza or to confirm viral shedding before symptoms.

4.1.3 Asymptomatic Infections

A small portion of individuals infected with influenza virus never get clinically ill. These asymptomatic individuals are infected with influenza, shed virus, and therefore have the potential to transmit to others, but never develop symptoms.

4.1.3.1 Seasonal Influenza

Several studies examined the percent of asymptomatic seasonal influenza infections. Data from three papers, Lau et al., Loeb et al., and Suess et al., were included in our analysis (Supplemental Information on influenza disease course). These three studies all used the same method for defining an asymptomatic

infection.[38] Individuals were considered to be asymptomatic if they were actively shedding influenza virus but were not experiencing any upper respiratory infection symptoms. Individuals that were exposed to influenza through a close contact (usually a family member) were monitored for influenza viral shedding to determine if an infection had occurred. Infected individuals were then monitored to determine whether or not symptoms developed. The three studies suggest that 13% of individuals infected with seasonal influenza virus experience an asymptomatic infection. [39,40,41]

4.1.3.2 Pandemic Influenza

Only one paper was identified that examined asymptomatic pandemic influenza infections. During the 2009 H1N1 pandemic, Papenburg et al. used the same techniques described by Lau et al., Loeb et al., and Suess et al. in which asymptomatic individuals that shared a household with symptomatic individuals were monitored for viral shedding.[42] Papenburg et al. found 9.4% of individuals that shed H1N1 influenza virus remained symptom free.

4.1.4 Symptomatic Infections

An influenza diagnosis encompasses a variety of symptoms that can manifest in different combinations within each individual. Many symptoms are shared by seasonal and pandemic influenza, but some are only produced by more severe pandemic infections. Symptoms associated with seasonal influenza include chills, cough, diarrhea, fatigue, fever, headaches, myalgia, nasal congestion, rhinorrhea, sore throat, and vomiting. Additionally, pandemic influenza can also cause abdominal pain, bronchospasms, chest pain, confusion, conjunctivitis, loss of appetite, nosebleeds, and seizures. Not every individual will experience all of the symptoms for each disease.

4.1.4.1 Seasonal and Pandemic Influenza

The prevalence of some influenza symptoms are also age dependent.[43] For example, children with seasonal influenza are significantly more likely to experience vomiting than are those who are 60 years and older. The prevalence of each influenza symptom varies between children, adults, and the elderly during seasonal and pandemic outbreaks (Supplemental Information on influenza disease course).

Data on the prevalence of symptoms were obtained from observational influenza studies and from the control subjects of anti-influenza neuraminidase inhibitor clinical trials. These studies recorded the number and/or percentage of people experiencing an influenza infection and the specific symptoms they developed. No data on pandemic influenza in the elderly was identified. [44]

---

38 A 2008 paper by Carrat et al. also reviewed this topic; however, it did not explain how "asymptomatic" infections were defined and was therefore excluded from our analysis. 4.1.5 Mortality

4.1.5.1 Seasonal Influenza

Almost all infected patients will fully recover. A small portion of illnesses, however, will end in death. Thompson et al. in 2003 analyzed and abstracted seasonal influenza data compiled by the National Center for Health Statistics (NCHS) from 1990-1998. These data were then used to estimate the rate of influenza-associated deaths by age groups (Supplemental Information on influenza disease course). The percent excess mortality of infected individuals ranges from 0.0002% for those between five and 49 years old to 0.02% for those older than 64.[45]

4.1.5.2 Pandemic Influenza

The mortality rate of pandemic influenza is both difficult to estimate or predict due to the limited number of past pandemic outbreaks. It is estimated that approximately 500 million people were infected with the 1918 Spanish flu and 50 to 100 million people perished as a result of infection.[46] During the 2009 H1N1 pandemic, there were anywhere from 43 to 89 million cases of influenza with resultant 9,000 to 18,000 deaths.[47] The percentage of influenza infections that resulted in mortality was approximately 5% during the 1918 pandemic and less than 0.05% during the 2009 pandemic (Supplemental Information on influenza disease course).

4.2 The SARS- and MERS-coronaviruses

Throughout this report, our use of the term "coronaviruses" or "CoVs" refers specifically to SARS-CoV, MERS-CoV, and SARS/MERS-like bat CoVs such as HKU4 and HKU5. Note, the four human coronaviruses that cause mild to moderate respiratory illnesses such as the common cold or croup (coronaviruses HKU1, OC43, 229E, and NL63) were not evaluated because these are not considered in the NSABB GoF Framework.

4.2.1 Biology of the Coronaviruses

Severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) are caused by SARS-associated (SARS-CoV) and MERS-associated coronavirus (MERS-CoV), respectively. Coronaviruses are positive sense, single-stranded RNA viruses. They are the largest of all RNA viruses, comprised of approximately 30 thousand nucleotides. Due to the length of its genome, coronaviruses can be less dependent on cellular proteins than other RNA viruses, enabling easier cross-species transmission.

Three groups of coronaviruses have been identified, all with distinct genetic and serological identities. While they are both beta-coronaviruses, MERS-CoV is from lineage B while SARS-CoV belongs to

lineage C.[48] Aside from SARS-CoV and MERS-CoV, coronaviruses that can infect humans cause common colds, lower respiratory tract infections, and diarrhea.[49,50]

4.2.2 Genome Structure of the Coronaviruses

The long SARS-CoV genome is broken into five major open reading frames (ORF), which are sections of nucleotides responsible for coding a peptide (Figure 4.1). Beginning at the five prime end, the first two ORFs, 1a and 1b, comprise two-thirds of the genome and encode the viral replicase genes, which encode proteins that are responsible for viral genome replication in the host cell. Further down the genome, ORFs encode genes for the structural proteins of SARS-CoV: spike (S), envelope (E), membrane (M), and nucleocapsid (N). These characterized ORFs are interspaced between several other ORFs that encode accessory genes. While the exact role of accessory genes is unknown, they are believed to contribute to viral pathogenesis and not replication.[51,52]

MERS-CoV has a similar genome structure, including viral replicase genes and structural proteins, as SARS-CoV.[53]

4.2.2.1 Structural Proteins and Particle Structure

The M glycoprotein is responsible for virus assembly. M proteins are the most abundant transmembrane protein in the viral envelope, where they interact with N proteins. N proteins self-associate to helically encapsidate the viral RNA and form the ribonucleoprotein complex (RNP). Together with M proteins, these N proteins mediate incorporation of the genome into budding virions for release. N proteins are highly immunogenic and their interaction with host cell proteins establishes pathogenicity. Envelope (E) proteins are a hydrophobic integral membrane proteins that serve as viroporins, which form ion channels in the envelope and therefore, play a central role in virus morphogenesis and assembly. E proteins are also credited with preserving the membrane's curvature for particle stability and infectivity.

Lastly, spike proteins are transmembrane fusion proteins responsible for effective viral entry into host cells. The N-terminal domain (S1) facilitates target receptor binding while the C-terminal domain (S2) ensures proper viral fusion. The S1 domain differs between coronavirus types and is largely responsible for host range. [54] Activated spike proteins induce the host immune response, including antibody neutralization and are the major antigenic determinants of MERS-CoV and SARS-CoV. [55,56,57,58]

The virion contains one copy of the viral genome encapsidated by N proteins in an RNP (Figure 4.5). A viral envelope surrounds the virion with structural proteins S, E, and M embedded in its membrane. Coronavirus has a crown-like appearance due to the protruding club-shaped spike proteins.[59]

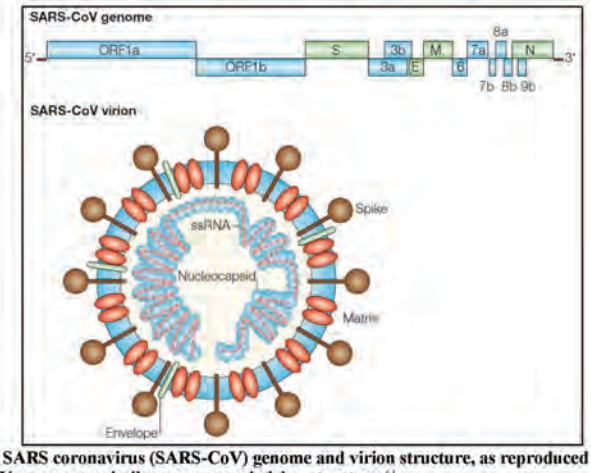

Figure 4.5. The SARS coronavirus (SARS-CoV) genome and virion structure, as reproduced from Perlman et al. [60] MERS-CoV possesses a similar genome and virion structure.[61]

4.2.3 Diversity of the Coronaviruses

Coronaviruses evolve rapidly, similar to all RNA viruses because polymerase infidelity results in amino acid mutations that alter transcription and potentially translation. Although these genetic mutations are minor and random, accumulation over time can lead to a new strain of virus. Some believe that the unusually large coronavirus genome leads to more mutations. Other studies have shown, however, that the genome encodes additional RNA processing and editing enzymes to correct for polymerase errors.[62,63,64]

64 Dudas G, Rambaut A (2015) MERS-CoV recombination: implications about the reservoir and potential for adaptation. *bioRxiv*

The coronavirus genome is also prone to homologous recombination. Recombination allows for genetic exchange between different virus strains during coinfection. The natural process facilitates cross-species transmission and the generation of new coronavirus species.[65,66,67]

Recombination can affect all viral proteins, but variation in the spike protein has a considerable effect on the virus due to its role in viral entry and host range. Changes in virulence, species transmission patterns, and host range are often a result of spike protein recombination.[68,69]

4.2.4 Host Range of the Coronaviruses

4.2.4.1 SARS-CoV

Before infecting humans, SARS-like CoVs infected an array of other animal species, including bats, palm civets, monkeys, domestic cats, raccoons, and ferrets. Bats are the virus's natural reservoir, however, palm civets are credited as the amplifying host that transmitted SARS-CoV to humans.[70]

Host specificity of SARS-CoV is heavily influenced by receptor recognition and hence, its spike protein. Viral sequencing suggests that the spike protein experienced heavy positive selection at the onset of the SARS outbreak.[71] Clinical data supports this premise, as SARS-CoV became increasingly pathogenic and transmissible among humans as the epidemic progressed; virus evolution through mutations to the spike protein were the likely cause.[72,73]

SARS-CoV entry is mediated by angiotensin I converting enzyme 2 (ACE2), the host cell receptor (Figure 4.2). Ordinarily ACE2 regulates host blood pressure. Host susceptibility to the SARS coronavirus is dependent on the binding affinity between the virus and the host-specific ACE2. Only two residue-altering mutations in the ACE2 gene were necessary to overcome the species barrier between palm civets and humans leading to sustained human infection.[74,75]

ACE2 is primarily found on ciliated cells in the lung epithelia, which explains the tropism of SARS-CoV to the lungs and the resultant respiratory illness. These receptors have also been detected in the heart, colon, and kidneys.[76,77] The absence of this receptor in muscle, blood or skin cells suggest that there is very little risk of infection if SARS-CoV is introduced in a cut.

4.2.4.2 MERS-CoV

The MERS-CoV spike protein, just as in SARS-CoV, largely determines the host range of the virus. Dipeptidyl peptidase 4 (DPP4), also known as CD26, was recently identified as the host receptor for viral entry. DPP4 is a widely expressed cellular protease tasked with assisting immune responses, glucose metabolism, and apoptosis. The glycoprotein is found on many cellular surfaces, including the kidneys, lungs, small intestines, and liver, which accounts for the virus's ability to cause systemic infection and shock.[78,79]

MERS-CoV infects a larger range of animals than does SARS-CoV. Transmission has occurred through close contact between humans and animals, most likely dromedary camels or bats.[80] The MERS coronavirus can also infect primates, horses, and goats, but is ineffective in smaller mammals such as ferrets, hamsters, and mice.[81] Host susceptibility to MERS is dependent on the binding affinity between the virus and the host-specific DPP4. Differences have been detected in DPP4 glycoproteins among mammals that may alter such affinity.[82]

There are no similarities between the structure or sequence of DPP4 and ACE2, the host receptor for SARS-CoV, which explains the distinct host ranges among the two coronaviruses. Further research suggests that differences in expression levels and locations of the receptors may account for the viruses' difference pathogenesis.[83]

4.2.5 SARS-CoV Epidemiology

SARS is an acute viral respiratory illness that develops into severe pneumonia. It is a contagious and virulent disease. Without treatment, the pneumonia may lead to respiratory failure and death.[84]

4.2.5.1 Incubation Period

The incubation period is the time between when an individual is exposed to a pathogen and when the first symptom manifests. During the incubation period of SARS and MERS, infected individuals probably cannot transmit the infection to others; therefore, longer incubation periods equate to a slower outbreak development.

The incubation period of SARS is was found to vary significantly between patients and during the 2003 pandemic, between countries. According to the World Health Organization (WHO), most countries experienced a median incubation period of four to five days and mean of four to 6 days with a minimum of one day and maximum of 14 days reported.[85] The primary literature is rich with studies on the incubation periods of SARS cases (Supplemental Information on CoV disease course). The literature

suggests a mean incubation period of 5.18 days and median of four days.[86,87,88,89,90] Donnelly found that 95% of patients experience onset of symptoms within 14.22 days.[91] The literature findings generally support the published reports from the WHO but presented a range of one to 18 days, capturing the variability of the SARS incubation period. No definitive explanations exist for the cause of the distribution of incubation period is so widespread, but difficulty identifying exposure, varying infectious doses, and multiple exposures are possible causes. Route of transmission may also affect the incubation period, but it is unclear why or how.[92,93,94,95,96]

4.2.5.2 Infectious Period

The infectious period is the disease stage when an infected individual can transmit the disease to others. The most widely accepted method of determining contagiousness is measuring viral shedding. Under this method, an individual is deemed infectious when they begin shedding virus and stops being infectious when the viral shedding ends.

Data on viral shedding and the infectious period of SARS is very limited. Cori et al. modeled the average infectious period in SARS patients to be 9.3 days.[97] Available literature agrees that viral shedding is low within the first few days following infection, meaning contagiousness is also low. The available research from Isakbaeva et al., Cheng et al., and Peiris et al. suggests the viral shedding peaks between day ten and day 14 following infection (Supplemental Information on CoV disease course).[98,99,100] However, Isakbaeva et al. also found viral shedding to persist for 26 days in a patient in the United States.[101] The Centers for Disease Control and Surveillance (CDC) recommends that while SARS patients are most contagious during their second week of illness, they should also limit contact with others for ten days after symptoms subside.[102]

4.2.5.3 Symptoms

SARS typically begins with influenza-like symptoms, including high fever, fatigue, sore throat, headache, and myalgia. Some patients also experience diarrhea, dry cough, and shortness of breath. As SARS progresses, most cases will develop into pneumonia.[103]

According to Donnelly et al., the most common symptom is fever, with 94% of cases reporting this symptom to the Hong Kong Department of Health. Influenza-like symptoms were second most common at approximately 72% of illnesses. Less than one quarter of patients displayed gastrointestinal symptoms such as diarrhea, vomiting, and abdominal pain. Approximately 88% of illnesses presented fever plus one other symptom.[104] Without treatment, the pneumonia may lead to respiratory failure and death.

4.2.5.4 Mortality

The overall case fatality-rate of the SARS outbreak is estimated at 11%, according to the WHO. Between age groups, rates vary from 0%-50%.[105] Christian et al. assessed the range to be between 0%- 40% with an overall fatality rate of 9.6%.[106] The high rate of mortality of SARS in the elderly is not accurately captured by the overall case-fatality rate. Although infection rates were similar, Wang et al. asserts that the fatality rate in those over 75 years old was 38% whereas no deaths occurred in those under 24 years.[107] Similarly, analysis by Donnelly et al. determined the case-fatality rate for persons under 60 years old to be 6.8% while the rate for over 60 years was 55%.[108] Advanced age is the most influential risk factor for SARS-associated death. In addition to age, diabetes mellitus and hepatitis B virus infection are other risk factors for death.

4.2.6 MERS-CoV Epidemiology

Middle East Respiratory Syndrome (MERS) is a respiratory infection that can develop into an acute severe respiratory illness. Many cases end in death, although most who succumb suffer from significant co-morbidities.

4.2.6.1 Incubation Period

According to the CDC, the incubation period of MERS can range from two to 14 days with a median of five days. As of July 2015, the WHO supports a median incubation period of 5.5-6.5 days.[109] Several additional literature sources were identified that describe the incubation period. Analysis by Cowling et al., Assiri et al., and Park et al. determined that the median incubation period of MERS is 6.07 days with a range from two to 15 days (Supplemental Information on CoV disease course). The literature, the WHO,

and the CDC recommendations concur that most patients begin experiencing symptoms within the first week of contact with the MERS coronavirus.[110,111,112]

4.2.6.2 Infectious Period

Limited and inconclusive information is available on the infectious period of MERS. Patients are considered infectious while they are shedding the virus, but time-specific data is lacking. They are not contagious during the incubation period, however patients may continue to shed virus after symptoms have subsided.[113,114,115] A study by Memish et al. reported that 76% of studied cases were still shedding virus 12 days after symptoms appeared. Additionally, analysis showed that sicker patients and those with significant comorbidities shed MERS-CoV for a longer period of time than standard cases.[116]

4.2.6.3 Symptoms

MERS symptoms range from mild to severe; patients display symptoms such as fever, cough, sore throat, shortness of breath, and myalgia that can advance to respiratory failure and septic shock. Approximately 20% of cases have presented as asymptomatic or very mildly symptomatic; it is unknown if asymptomatic cases are contagious.[117]

4.2.6.4 Mortality

The case-fatality rate of MERS is estimated at almost 40%.[118] There is a clear positive correlation between increasing age and case-fatality rate. According to the WHO, the median age of MERS cases is 50 years old, with a range from nine months to 99 years.[119] Assiri et al. reported that among cases in Saudi Arabia, the case-fatality rate was 75% in patients over 60 years of age while there were no fatalities in patients younger than 19 years.[120]

Comorbidities also increase a patient's susceptibility to MERS-CoV. A large percent of MERS fatalities occur in patients with underlying medical conditions, such as diabetes and hypertension as well as chronic renal, lung, and cardiac disease.[121]

4.3 An Overview of GoF Research

This section provides an overview of all Gain of Function (GoF) experimental approaches that are regularly used in the fields of coronavirus and influenza virus research. Our definition of "Gain of Function" includes all experimental approaches that are reasonably anticipated to lead to one or more of the following phenotypic changes, as defined in the NSABB's "Framework for Conducting Risk and Benefit Assessments of Gain of Function Research":

- Enhanced pathogen production as a result of changes in the replication cycle or growth,
- Enhanced morbidity and mortality in appropriate animal models,
- Enhanced transmission in mammals (e.g., increased host or tissue range, altered route of transmission, infectivity above a certain threshold determined in an appropriate animal model),
- Evasion of existing natural or induced immunity, and
- Resistance to drugs or evasion of other medical countermeasures such as vaccines, therapeutics, diagnostics.

These findings are based on two data sources: (1) a comprehensive review of the scientific literature involving influenza viruses and coronaviruses and (2) interviews with influenza virus and coronavirus researchers. Within the field of coronavirus research, our literature review included studies involving:

- SARS-CoV,
- MERS-CoV, and
- SARS- or MERS-like animal CoVs, including bat CoVs and civet CoVs.

We did not examine the scientific literature involving the four human coronaviruses that cause mild to moderate respiratory illnesses such as the common cold or croup: coronaviruses HKU1, OC43, 229E, and NL63. We note that throughout this report, our use of the term "coronaviruses" or "CoVs" refers specifically to SARS-CoV, MERS-CoV, and SARS/MERS-like animal CoVs such as HKU4 and HKU5. We identified approaches involving coronaviruses that are reasonably anticipated to lead to the following phenotypic changes:

- Enhanced pathogen production as a result of changes in the replication cycle or growth,
- Enhanced morbidity and mortality in appropriate animal models,
- Altered host range, and
- Evasion of therapeutics in development.

As current animal models for studying coronaviruses do not support transmission between animals, this field does not include any approaches that lead to enhanced transmission in appropriate animal models. Additionally, because there is no widespread population immunity to the coronaviruses and there are no licensed coronavirus vaccines, this field does not include any approaches that lead to evasion of existing natural or induced immunity. Finally, we did not identify any coronavirus research that is reasonably anticipated to lead to evasion of diagnostics or of vaccines in development. (We note that there are currently no FDA-approved vaccines or therapeutics for coronaviruses.)

Within the field of influenza research, our literature review included studies involving:

- Human seasonal strains: currently circulating and historical influenza A H1N1 and H3N2 viruses and influenza B viruses,
- Human pandemic strains: the 1918 H1N1, 1957 H2N2, 1968 H3N2, and 2009 H1N1 viruses,
- Swine-origin strains: H3N2v and others, and
- Avian-origin strains: H5N1, H7N9, H9N2 and others.

We identified approaches involving influenza viruses that are reasonably anticipated to lead to the following phenotypic changes:

- Enhanced pathogen production as a result of changes in the replication cycle or growth,
- Enhanced morbidity and mortality in appropriate animal models,
- Altered host range,
- Enhanced transmission in mammals,
- Evasion of existing natural or induced immunity,
- Evasion of therapeutics, and
- Evasion of vaccines in development.

We note that we are using the term "therapeutics" to include drugs that directly target viruses (e.g., influenza neuraminidase inhibitors), monoclonal antibody-based therapeutics, host immune modulators, and any other type of antiviral therapeutic. We did not identify any influenza research that is reasonably anticipated to lead to evasion of diagnostics.

We note that passaging of influenza viruses and coronaviruses in cells is essential for any experimental work involving live viruses, both to prepare virus stocks for experimental use and to conduct infection experiments. This applies to alt-GoF approaches, such as characterization of wild type viruses, as well as to GoF approaches. Because of the high mutation rates of RNA viruses, including influenza viruses and coronaviruses, such passaging inevitably selects for higher-yield viruses.[122] However, within the "enhanced virus production" phenotypic category, this analysis is restricted to those approaches that deliberately seek to enhance virus production through serial passaging, targeted genetic modification, or other approaches.

Below we briefly summarize the experimental approaches we identified within each phenotypic category, describing the experimental manipulation, virus strains that are used, and the scientific outcomes of each approach.

4.3.1 Coronaviruses

4.3.1.1 Enhanced Pathogen Production as a Result of Changes in the Replication Cycle or Growth

Serial passaging of CoVs in cell culture leads to the generation of higher-yield viruses. This approach has been performed using low-yield bat CoV strains to generate higher-yield strains that are suitable for experimental use. As SARS and MERS naturally grow well in the standard cell culture systems that are used in the field, researchers are not serially passaging either virus in cell culture to enhance virus production.

[122] Parvin JD *et al* (1986b) Measurement of the mutation rates of animal viruses: influenza A virus and poliovirus type 1. *Journal of virology* 59: 377-383

4.3.1.2 Altered Host Range

Several experimental approaches alter the host range of CoVs. One approach involves "Spike swapping," which is targeted genetic modification to replace all or part of the coronavirus Spike protein, a viral surface protein that mediates virus entry into cells and is a critical determinant of host restriction, with the Spike protein from another CoV species. This manipulation leads to the generation of a recombinant, chimeric CoV that may exhibit altered host tropism relative to the parental CoV species. The purpose of these experiments is three-fold:

- Introducing the SARS Spike protein into the backbone of bat CoVs, which do not efficiently infect standard cell culture lines or animals, enables the chimeric virus to infect cells/animals, thus creating a tool that can be used to study the biology of the bat CoV,
- Chimeric viruses are used as tools to test whether CoV therapeutics and vaccines are broad-spectrum, capable of protecting against potentially emerging SARS/MERS-like bat CoVs as well as SARS and MERS, and
- Testing the ability of chimeric CoVs to infect various types of cells and animals reveals the breadth of host tropism conferred by a given Spike protein, and comparing the sequences of parental and donated Spike proteins with different host tropism can uncover amino acid residues that mediate host restriction.

A second approach involves serial passaging of CoVs in mice, which leads to the generation of viruses that have adapted to more efficiently infect and cause disease in mice. The purpose of this experiment is two-fold:

- Mouse-adapted strains are experimental tools that are used for the study of disease pathogenesis and for testing the efficacy and safety of vaccines and therapeutics, and
- Comparing the sequences of the mouse-adapted and the parental strain leads to the identification of mutations that are associated with adaptation, which provides a foundation for follow-up studies investigating the mechanistic basis of virus adaptation to new hosts.

SARS CoV has been passaged in mice by multiple research groups to generate several different mouse-adapted strains; chimeric bat-SARS CoVs have also been passaged in mice. Serial passaging of MERS virus in mice, in order to generate a mouse model for the study of MERS, is ongoing.

A third approach involves targeted mutagenesis to introduce mutations that are associated with altered host tropism, which has been performed using SARS CoV. These mutations may have been discovered through a GoF approach, such as serial passaging, or through an alt-GoF approach, such as comparative sequence analysis. This experiment is performed to demonstrate that the mutation(s) are necessary and sufficient to alter host tropism, which provides a foundation for follow-up studies investigating the phenotypic traits underlying virus adaptation to new hosts.

4.3.1.3 Enhanced Morbidity and Mortality in Appropriate Animal Models

Several experimental approaches enhance the fitness or virulence of CoVs in cell culture or laboratory animal model systems, respectively. First, serial passaging of CoVs in mice leads to the generation of viruses with both enhanced infectivity to and virulence in mice. Because of the specificity of virus-host

interactions that are important determinants of host tropism and pathogenicity, this adaptation often translates to reduced virulence in humans. The purpose of this experiment is two-fold:

- Enhancing the virulence of the virus in mice is an important aspect of creating a mouse model that replicates human disease pathology, which is needed for the study of disease pathogenesis mechanisms and the testing of medical countermeasures, and
- Comparing the sequences of the mouse-adapted and the parental strain leads to the identification of mutations that are associated with enhanced virulence, which provides a foundation for follow-up studies to elucidate the mechanistic basis of virulence. This information can also benefit public health by identifying new potential targets for therapeutics or for attenuation, in order to create attenuated vaccine viruses.

A second approach involves targeted genetic modification of viruses to introduce mutations that are associated with enhanced virulence, which is performed to demonstrate that the mutation(s) are necessary and sufficient to enhance virulence. As above, this information provides a foundation for follow-up studies to elucidate the mechanistic basis of virulence.

A final approach involves serial passaging of attenuated viruses in cells or in animals, in order to determine whether viruses can recover fitness/virulence upon growth in appropriate model systems. This approach is performed using attenuated viruses that could be used as live attenuated vaccines (LAVs). Because LAVs with an ability to recover fitness during growth *in vivo* could cause adverse outcomes in people, a negative result is an important indicator of safety for any live attenuated vaccine in development.

4.3.1.4 Evasion of Therapeutics in Development

Serial passaging of a virus in cells in the presence of a therapeutic may lead to the emergence of viruses that are resistant to inhibition/neutralization by that therapeutic. This type of experiment has been performed using SARS CoV, in order to select for escape from monoclonal antibody therapeutics and other types of therapeutics. The purpose of the experiment is to understand whether and how readily resistance will arise in response to selective pressure from the therapeutic and to identify mutations that are associated with resistance to the therapeutic, which provides a foundation for follow-up studies investigating the mechanisms underlying antiviral activity and antiviral resistance. Because there are no FDA-approved therapeutics for CoVs, this approach has exclusively been applied to the study of therapeutics in development.

4.3.2 Influenza viruses

4.3.2.1 Enhanced Pathogen Production as a Result of Changes in the Replication Cycle or Growth

Several experimental approaches lead to enhanced production of influenza viruses. The first approach involves reassortment between a wild type strain and an attenuated, high-yield vaccine backbone strain to generate a "Candidate Vaccine Virus" (CVV), which comprises the HA and NA genes from the wild type strain and the remaining six "internal genes" from the vaccine backbone strain and exhibits higher levels of growth than the parental, wild type virus. CVVs are attenuated and exhibit higher levels of growth relative to the parental, wild type virus. CVVs may be generated through classical reassortment methods, which involve co-infection of eggs or cells with the wild type strain and the vaccine backbone strain followed by antibody-based selection for viruses with the correct surface antigens or through reverse

genetics.[123] These approaches are currently used for the production of influenza vaccines in eggs or cells – high-yield CVVs serve as the basis for the vaccine strains that are used by manufacturers for large-scale production. In addition, comparing the sequences of CVVs with different growth properties can lead to the identification of mutations associated with high growth.

The second approach involves serial passaging of viruses in cells, which selects for higher-yield viruses. This approach is also a core aspect of the current production of influenza vaccines in eggs or cells. Specifically, manufacturers serially passage CVVs in eggs or cells to increase CVV yields and to optimize growth and infection conditions in order to create a vaccine seed strain that is used for large-scale production of vaccine viruses. The serial passaging approach is also used in academic research, primarily involving vaccine backbone strains and CVVs but occasionally involving wild type viruses. In addition to supporting vaccine development, the goals of this experiment could be to identify mutations associated with high yield, which provides a foundation for follow-up studies investigating the mechanistic basis of high growth in cells or eggs.

Third, forward genetic screens, which involve random mutagenesis of viruses followed by limited passaging to select for mutants with high growth properties, enable the identification of mutations that confer high growth to viruses. Forward genetic screens involving vaccine backbone strains and CVVs lead to the identification of mutations that are sufficient to enhance the yields of vaccine viruses.

A final approach involves targeted mutagenesis of viruses to introduce mutations that are associated with high growth. These mutations may have been discovered through a GoF approach, such as serial passaging or a forward genetic screen, or through an alt-GoF approach, such as comparative analysis of wild type sequences. This experiment is performed to demonstrate that the mutation(s) are necessary and sufficient to enhance virus production, which provides a foundation for follow-up studies investigating the mechanistic basis of the high-growth phenotype.

We note that experimental approaches involving targeted genetic modification of the viral polymerase complex of avian viruses to render it more "human-like" (through site-directed mutagenesis or reassortment between human and avian viruses) is also likely to enhance virus replication. However, as the primary goal of those studies is to gain insight into the mechanisms underlying adaptation of avian viruses to mammals, we discuss those studies in the "enhanced transmission in mammals" section.

4.3.2.2 Altered Host Range

Several experimental approaches lead to the generation of viruses with altered host range. First, serial passaging of viruses in mammalian cells or tissues or in laboratory animals selects for viruses with enhanced growth in cells or enhanced infectivity to animals, respectively. This type of serial passaging experiment involves "forced" passaging, meaning that the experimenter directly transfers infected material, in the form of cell culture supernatant or homogenates of infected tissue, to the subsequent cell culture dish or animal. Forced serial passaging is carried out for two purposes: (1) to identify mutations that arise during adaptation of animal-origin viruses (i.e., avian and swine viruses) to mammals, which provides a foundation for follow-up studies investigating the evolutionary mechanisms driving adaptation to mammalian hosts and the mechanistic basis of mammalian adaptation, and (2) to develop an mouse model for the study of a particular virus. Avian and swine viruses are used for studies that seek to understand the mechanisms underlying mammalian adaptation, and human seasonal viruses are primarily used for studies that aim to generate new mouse models.

---

[123] Use of classical reassortment methods to generate CVVs may lead to the generation of a 5:3 reassortment strain which includes the HA, NA, and one additional gene from the wild type strain and the remaining five genes from the vaccine backbone strain.

A second approach involves deliberate genetic modification of viruses, namely site-directed mutagenesis and/or reassortment, to introduce genetic traits that may enhance fitness/infectivity in mammals. These mutations or reassortment gene combinations may be random (i.e., for a forward genetic screen) or may have been previously shown to be associated with mammalian adaptation or an underlying phenotype, such as a preference for host receptors decorated with 'human-like' sialic acid moieties. Notably, genetic traits that are associated with mammalian adaptation may be discovered through GoF approaches, such as serial passaging, or alt-GoF approaches, such as comparative sequence analysis of avian viruses isolated from human versus poultry infections. Collectively, the deliberate genetic modification approach is used to discover new genetic traits that contribute to mammalian adaptation and to confirm that particular genetic traits are necessary and sufficient to enhance fitness/infectivity in mammals. Animal viruses, including avian and swine viruses, are used exclusively for these studies.

4.3.2.3 Enhanced Transmission in Mammals

Several experimental approaches lead to the generation of viruses with enhanced transmissibility in mammals. First, serial passaging of viruses in animals with selection for transmission leads to the generation of viruses with enhanced transmissibility in mammals. This type of serial passaging experiment can involve selection for contact transmission, during which the primary (directly inoculated) and secondary hosts are co-housed, or for airborne transmission, during which the primary and secondary hosts are separately housed in special isolator cages that prevent direct contact between animals but allow for air exchange between cages. These studies seek to identify mutations that are sufficient to enhance transmissibility, which provides a foundation for follow-up studies that investigate the mechanistic basis of transmissibility in mammals. Animal viruses, including avian and swine viruses, are used exclusively for these studies.

A second approach involves deliberate genetic modification of viruses, namely site-directed mutagenesis and/or reassortment, to introduce genetic traits that may enhance transmissibility in mammals. These mutations or reassortment gene combinations may be random (i.e., for a forward genetic screen) or may have been previously shown to be associated with transmissibility or an underlying phenotype, such as an increase in the stability of the HA protein. Notably, genetic traits that are associated with transmissibility may be discovered through GoF approaches, such as serial passaging, or alt-GoF approaches, such as forward genetic screens to identify mutations that alter HA stability performed using *in vitro*, virus-free systems. Collectively, the deliberate genetic modification approach is used to discover new genetic traits that contribute to transmissibility and to confirm that particular genetic traits are necessary and sufficient to enhance transmissibility in mammals. Animal viruses, including avian and swine viruses, are used exclusively for these studies.

4.3.2.4 Enhanced Morbidity and Mortality in Appropriate Animal Models

Akin to the enhanced transmission phenotype, both serial passaging and deliberate genetic modification approaches can lead to the generation of viruses with enhanced morbidity and mortality in appropriate animal models. Serial passaging of viruses in animals selects for viruses with enhanced virulence and is used for three purposes. First, serial passaging is utilized to develop animal models for studying the mechanistic basis of flu-associated morbidity/mortality and for medical countermeasure development (as adapting a virus to an animal typically enhances its virulence in that host). Second, this approach enables the identification of mutations that are associated with enhanced fitness/virulence, which provides a foundation for follow-up studies that investigate the mechanistic basis of pathogenicity. These studies can also provide insight into host mechanisms underlying disease pathology by correlating host immune responses with morbidity and mortality measures. Third, the serial passaging approach is used to determine whether attenuated strains are capable of recovering virulence upon passage *in vitro* or *in vivo*.

This third type of serial passaging study may be carried out using live attenuated influenza vaccine (LAIV) candidates, as an important aspect of safety testing prior to human clinical trials. In addition, these studies may be conducted using strains with fitness defects arising from the acquisition of antiviral resistance or other GoF phenotypes, in order to gain insight into the likelihood that these strains will persist and spread in nature. All types of serial passaging studies may be performed with seasonal or animal (i.e., avian and swine) viruses, and animals such as mice, ferrets, and swine may be used. Of note, serial passaging studies involving attenuated strains simply increase the human health risk of the attenuated strain to approach that of wild type strains.

A second approach involves deliberate genetic modification of viruses, through either site-directed mutagenesis or reassortment, to introduce genetic traits that are expected to enhance pathogenicity. As above, these mutations or reassortment gene combinations may be random (e.g., for a forward genetic screen) or may have been previously shown to be associated with a phenotype underlying pathogenicity, such as evasion of a particular innate immune response. Traits that are associated with enhanced pathogenicity may be discovered through GoF approaches, such as serial passaging, or alt-GoF approaches, such as random mutagenesis followed by screening for attenuated virulence (Loss of Function). Collectively, the deliberate genetic modification approach is used to discover new genetic traits that contribute to pathogenicity and to confirm that particular genetic traits are necessary and sufficient to enhance virulence in mammals. These studies are performed using human seasonal viruses, the 1918 H1N1 pandemic virus, and animal viruses.

We note that the relationship between viral fitness and pathogenicity is complex and that many of the viral traits that contribute to fitness, either directly or indirectly, mediate pathogenicity. As a result, serial passaging of viruses in animals may select for both enhanced fitness and enhanced virulence. However, enhanced viral fitness *in vivo* does not necessarily translate to high pathogenicity, as seasonal influenza viruses do not display the morbidity and mortality displayed during infections with zoonotic influenza viruses such as H5N1, but grow to a high titer.

4.3.2.5 Evasion of Existing Natural or Induced Adaptive Immunity

Several experimental approaches can lead to the generation of viruses that evade existing natural or induced immunity. First, serial passaging of viruses in the presence of cognate antibodies may lead to the acquisition of mutations that allow the virus to escape neutralization by the antibody. This experiment can be performed in cell culture or in animals that have been vaccinated or previously exposed to influenza viruses. The second approach involves deliberate modification of the influenza HA protein, the immunodominant influenza protein and the primary component of influenza vaccine, to introduce mutations that may lead to antigenic change. In this case, the mutations may be random (i.e., in the context of a forward genetic screen), previously identified through a GoF approach such as serial passaging, or previously identified through an alt-GoF approach such as comparative analysis of wild type sequences. When either approach is performed using recently or currently circulating seasonal influenza viruses or using seasonal viruses that have recently served as the basis for vaccine strains, the end result is the generation of a mutant strain that cannot be neutralized by existing natural or induced immunity, respectively. These studies aim to identify amino acid substitutions that lead to antigenic change and to define the evolutionary pathways by which those substitutions arise, which provides a foundation for follow-up studies investigating the evolutionary mechanisms driving antigenic drift and the molecular basis of antigenic differences between strains.

Because human populations do not have widespread immunity to the 1918 H1N1 pandemic virus or to animal influenza viruses (i.e., avian viruses and swine viruses), no approaches involving these viruses meet this phenotypic criterion.

4.3.2.6 Evasion of Vaccines in Development

Serial passaging of a virus in cells in the presence of animal sera produced in response to a candidate vaccine or in animals vaccinated with a candidate vaccine may lead to the emergence of viruses that are resistant to neutralization by that vaccine. This approach is used to test whether and how readily viruses can evolve to evade vaccines in development, for example new vaccine platforms that are more broad-spectrum or resistant to drift than current influenza vaccine platforms, which is an important indicator of the potential field efficacy of the vaccine. Most of these experiments involve next-generation influenza vaccine candidates targeting epitopes other than the globular head domain of the hemagglutinin (HA) protein, the target of current influenza vaccines. Given that the globular head domain of HA is the immunodominant protein of influenza viruses and that these next-generation vaccines are not yet widely available, strains that can overcome the protection afforded by these vaccines are expected to pose a minimal increase in human health risk relative to wild type strains.

Because seasonal influenza vaccines are updated annually, approaches that lead to the generation of vaccine strains that are no longer neutralized by vaccine-induced antibodies are more appropriately described by the "evasion of existing induced immunity" phenotype. In addition, we did not identify any studies involving H5N1 viruses that would be expected to lead to the generation of viruses that cannot be neutralized by the pre-pandemic H5N1 vaccine in the national stockpile.

4.3.2.7 Evasion of Therapeutics

Several approaches may lead to the generation of viruses that are resistant to therapeutics. The classical approach involves serial passaging of viruses in the presence of a therapeutic, which may lead to the acquisition of mutations that allow the virus to evade inhibition by the therapeutic. This approach is performed to determine whether and how readily a virus evolves resistance in response to selective pressure from a therapeutic and to identify mutations that confer resistance, which provides a foundation for follow-up studies investigating the mechanism of action of the therapeutic and the mechanistic basis of antiviral resistance. When passaging experiments are performed using a new therapeutic candidate with an unknown viral target, this information also helps to identify the therapeutic target, as resistance mutations are most likely to arise in the target protein. Of note, the acquisition of resistance to novel classes of therapeutics is not expected to confer cross-resistance to existing antivirals (i.e., adamantanes or neuraminidase inhibitors). Thus, when these experiments involve drug candidates within new classes of therapeutics, which are not yet widely available, no increase in human health risk is posed by resistant strains. Serial passaging approaches have been performed using cell culture, animal models, and (rarely) human challenge experiments.

The second approach involves deliberate modification of antiviral target proteins to introduce mutations that may confer antiviral resistance. In this case, the mutations may be random (i.e., in the context of a forward genetic screen), previously identified through a GoF approach such as serial passaging, or previously identified through an alt-GoF approach such as comparative analysis of wild type sequences. Similar to serial passaging experiments, these experiments provide a foundation for follow-up studies investigating the mechanistic basis of antiviral resistance. Both types of GoF approaches have been performed using human seasonal viruses, human pandemic strains (i.e., the 1957 H2N2 pandemic virus), and animal-origin strains. (We note that human challenge experiments have only been performed using human seasonal strains.)

4.3.2.8 Reassortment

Several experimental approaches can be used to assess the genetic compatibility and fitness of viruses following reassortment. While the phenotypic consequences of reassortment events between two viruses

cannot be predicted with certainty, reassortant strains may exhibit enhanced fitness, pathogenicity, and/or transmissibility relative to one or both parental strains. (Notably, reassortant strains may also display *reduced* fitness, pathogenicity, and/or transmissibility relative to parental viruses.) In the laboratory, reassortant viruses can be generated through reverse genetics, which involves the deliberate mixing of gene segments from two or more viruses in one or multiple combinations or through co-infection of cells or animals with two viruses. Follow-up studies may be performed to evaluate pathogenicity, infectivity, and/or transmissibility of viable reassortants. Collectively, these approaches assess the viability and phenotypic properties of various reassortment viruses. This information provides a foundation for studies investigating mechanisms governing reassortment and informs the potential for reassortant viruses to emerge in nature and the potential public health consequences of such an emergence event.

5 Historical Context of Outbreaks of Influenza, SARS and MERS

5.1 Purpose and Context

In this section, we review the history and current status of influenza, SARS, and MERS to provide context for evaluating the potential risks and benefits associated with GOF studies. Naturally-occurring epidemics and pandemics present risks to human and animal health and burdens to public health infrastructure. Such risks are pertinent to the ongoing deliberative process on the risks and benefits of GOF research as they help to establish the existing risks associated with infectious diseases to which the risks associated with GOF studies might be compared. This historical perspective will also inform evaluations of the potential benefit of interventions to reduce the burden of these diseases on society; the greater the harm that these diseases have inflicted, the greater the potential benefit to society of mitigating their harm.

To the extent available, we have gathered data on past outbreaks of these diseases and the morbidity, mortality, and economic harm that they have inflicted. For seasonal influenza, these data should provide a solid baseline for understanding the potential benefits of reducing the burden of this disease that continues to afflict public health annually. Caution should be used when reviewing the data on outbreaks of pandemic influenza strains and the human coronaviruses because the disease caused by each new strain has unique attributes that influence its extent and severity. The next outbreak from a newly emergent influenza virus or coronavirus could be as severe, not nearly as severe as, or more severe than any of the historical outbreaks and there is no science-based means to determine the severity a priori.

For example, although the 1918 influenza outbreak is often held up as the exemplar of the type of pandemic that researchers are trying to prevent, detect early, or mitigate, the severity and extent of the outbreak may be only partially explained by its unique biology. This pandemic occurred in the waning years of a world war, when the nutritional status and overall health of the global population was compromised and when living conditions for the most vulnerable populations were poor (in this case, younger adults). Perhaps more importantly, public health systems (which rely on the public's understanding of the seriousness of infectious disease threats) are far more robust today, and therefore today's social distancing measures and mass vaccination may greatly mitigate the consequences of an outbreak. Conversely, the society of the early 20th century was less reliant on complex networks to provide food, security, water, and sanitation services, which could crumble in the face of an outbreak of a disease that kills a significant number of otherwise healthy adults, leading to secondary deaths from starvation or social disorder.

Note that, although the findings in this section provide historical background and context for the viruses studied, they do not directly provide the epidemiological parameters used in the biosafety risk assessment described in Chapter 6. Because the biosafety risk assessment was done parametrically, for each virus a range of values was used for each of the parameters. In certain cases, the values from historical outbreaks described here are used to provide an upper or lower bound for an epidemiological parameter. However, in general the ranges of values used in the biosafety risk assessment are broader, to account for the epistemic uncertainty in some of the values, to encompass all potentially possible naturally occurring strains, and to encompass the range of gain-of-function modifications that may be done to them. Further information on the range of values used in each of the biosafety models is described in the Supporting Information section for each model.

5.2 Severe Acute Respiratory Syndrome

5.2.1 Summary of Findings

- In 2003, an outbreak of SARS occurred in several Asian countries and Canada, causing nearly 10,000 illnesses and 1,000 deaths, with a disproportionate burden on the elderly,
- Most survivors suffer from long term physical and mental morbidities,
- The outbreak was responsible for $30-100Bn in economic losses, and
- No human cases of SARS have been reported since 2004.

5.2.2 Background

Severe acute respiratory syndrome (SARS) is a viral respiratory disease of zoonotic origin, caused by a coronavirus identified as SARS-associated coronavirus, or SARS-CoV. Despite ample research, the natural reservoir of SARS-CoV has not been documented conclusively. The Himalayan masked palm civet (*Paguma larvata*), a delicacy in southern China, is commonly attributed as the human transmission source, but other Chinese delicacies, such as ferret badger (*Melogalemoschata*), as well as domestic cats (*Felis domesticus)*, ferrets (*Mustela putorius furo*), and bats (*Rhinolophus)* have also been laboratory-confirmed as virus reservoirs.[124]

SARS typically begins with flu-like symptoms, including high fever, fatigue, sore throat, headache, and myalgia. Some patients also experience diarrhea, dry cough, and shortness of breath. As SARS progresses, most cases will develop into pneumonia. The disease spreads through close contact between people, mainly by droplet spread of infectious fluids.[125] Without treatment, the pneumonia may lead to respiratory failure and death.

5.2.3 Initiation of the SARS Outbreak

In November 2002, atypical pneumonia of an unknown cause was reported in two patients in Fushan City, southern Guangdong Province, China. Soon after, similar cases were reported in five other Guangdong cities.[126] The virus remained in China until February 2003 when a physician who had been treating SARS patients traveled from Guangdong to a hotel in Hong Kong. There he infected ten others from various countries who then continued traveling, bringing the virus with them to Ireland, Canada, Vietnam, Singapore, and the United States (Figure 5.1).[127]

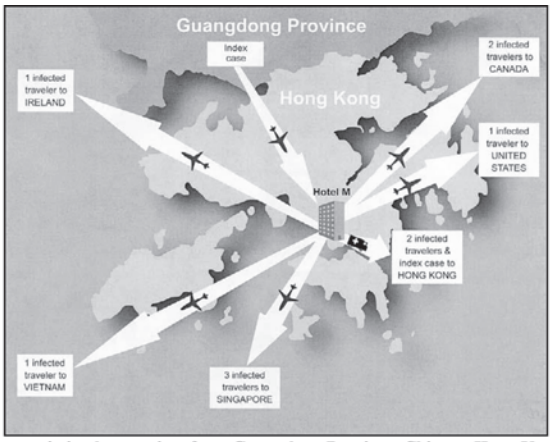

Figure 5.1. SARS transmission by a patient from Guangdong Province, China to Hong Kong and then to global travelers reproduced from Christian MD et al.[128]

These cases sparked a global outbreak. Within weeks, the communicable illness spread to 37 countries around the world and became recognized as the SARS epidemic of 2003.[129] Figure 5.2 below shows the explosiveness of the outbreak after the international transmission began.[130]

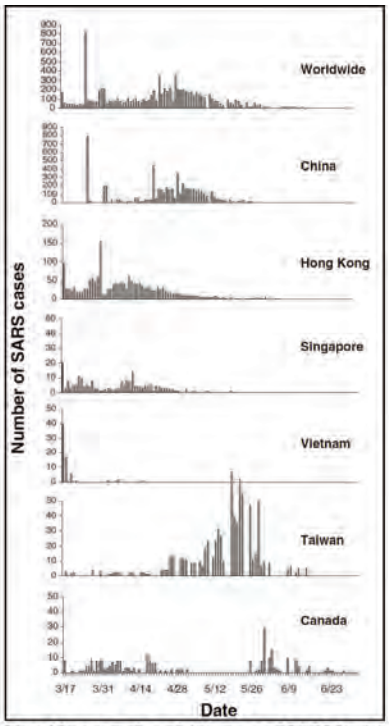

Figure 5.2. Reproduced from Chan-Yeung et. al, probable cases of SARS by date of onset or reporting worldwide.[131]

SARS is known to transmit through close person-to-person contact and droplet spread, however large, localized outbreaks suggest additional methods of transmission. Hong Kong's index case can be traced to an outbreak in a large apartment complex, Amoy Gardens, where 329 residents became infected.[132] The index case did not contact all three-hundred residents which, with the ability of SARS to remain viable in feces, presents the possibility of fecal-droplet transmission through the plumbing system of the apartment complex.[133]

The CDC also investigated "super spreaders" which are believed to be highly infectious index cases such as the Guangdong doctor that traveled to a hotel in Hong Kong and the resultant rapid outbreak in Canada. Possible explanations included a higher SARS-CoV infectious load, aerosolized transmission that allowed the particles to travel further, and increased age or previous illness that masked the SARS

132 Ibid.
133 Christian MD *et al* (2004) Severe acute respiratory syndrome. *Clin Infect Dis* 38: 1420-1427

infection. Rapid transmission by super spreaders is credited with initiation and continuation of the SARS outbreak.[134]

5.2.4 Morbidity and Morality

According to the World Health Organization (WHO), there were 8,098 SARS cases reported worldwide during the 2003 epidemic, which resulted in 744 deaths.[135] Approximately 30% of cases are believed to have occurred in healthcare workers due to the necessity of close contact in transmission.[136] In the United States, there were only eight laboratory-confirmed cases and no SARS-associated deaths. All eight patients had traveled to SARS-infected regions, but did not further transmit the disease upon returning to the US.[137]

The WHO estimates the overall case fatality rate of the SARS outbreak to be 11%, with a range of 0%-50% among age groups.[138] Another study estimates the range to be between 0%- 40% with an overall fatality rate of 9.6%.[139]

The overall fatality rate, however, minimizes the significant difference that occurred between age groups. SARS disproportionately kills older people and although the incidence rates did not differ amongst age groups, the mortality rate in those over 75 years old was 38% whereas no deaths occurred in those under 24 years.[140] Advanced age is the most influential risk factor for SARS-associated death. One study determined the case fatality rate for persons under 60 years old to be 6.8% while the rate for over 60 years was 55%.[141] Another study estimated the average case fatality rate at 45% for persons over 60 years.[142] These statistics are provided in Table 5.1 below. All affected regions experienced similar age-specific trends with a large variance between groups, as can be seen in Figure 5.3 from Anderson et al.

Table 5.1. SARS Case Fatality Rates Among Age Groups

[146] Anderson RM *et al* (2004) Epidemiology, transmission dynamics and control of SARS: the 2002-2003 epidemic. *Philosophical transactions of the Royal Society of London Series B, Biological sciences* 359: 1091-1105.
[147] Chan-Yeung M, Xu R-H (2003) SARS: epidemiology. *Respirology* 8: S9-S14

Overall mortality rates varied from 0% to 17.1% by region. As the epidemic proceeded, these rates began to climb. Regions affected early by SARS, such as Guangdong, had case fatality rates ranging from 4% to 10%; regions affected later in the outbreak experienced higher rates, upwards of 13% to 17%.[148] One explanation for this trend is a younger population in regions affected earlier by the virus. Another possibility is evolution towards a more virulent strain, providing the virus with greater opportunities for transmission. Worsened symptoms increase the likelihood of droplet spread as well as the need for more medical treatment and hence, risk of human transmission.[149]

5.2.5 Long-Term Morbidity

SARS survivors experienced significant long-term morbidity. Mak et al. used the MOS 36-Item Short Form (SF-36), a functional outcome assessment, to measure the quality of life of survivors post-illness in Hong Kong. The study found that SARS survivors performed poorer in all eight quality of life categories than the normal population (Table 5.3).[150] In 2009, the Chinese media reported that 300 survivors declared continued complications from their illness. Approximately 60% still suffered from medical issues, including avascular necrosis and pulmonary fibrosis, and 80% could no longer work. Chronic depression was also reported.[151]

Table 5.3. Quality of Life Based on Eight Domains of the SF-36 Assessment Between SARS Survivors and the Normal Population 30 Months After the Sars Epidemic. Table Reproduced from Mak et. al[152]

Quality of Life	SARS Subjects (n=90)	HK Population normative values	P[a]
Physical functioning	75.17±22.77	91.83±12.89	<.001**
Role limitations due to physical health	43.54±46.39	82.43±30.97	<.001**

151 Xiang YT *et al* (2014) Outcomes of SARS survivors in China: not only physical and psychiatric co-morbidities. *East Asian archives of psychiatry : official journal of the Hong Kong College of Psychiatrists = Dong Ya jing shen ke xue zhi : Xianggang jing shen ke yi xue yuan qi kan* 24: 37-38

152 Mak IWC *et al* Long-term psychiatric morbidities among SARS survivors. *General Hospital Psychiatry* 31: 318-326

Many SARS survivors suffer from mental morbidity. Several studies have examined the psychiatric status of survivors at different time points, populations, and locations. Because of these differences, the percentage of survivors with a psychiatric disorder has fluctuated, however, the burden of mental illness (Table 5.4). Health care workers also tended to have higher stress levels and depressive symptoms than non-workers, with 90% qualifying as a potential psychiatric case.[153]

Table 5.4. Percentage of the Measured Population with a Psychiatric Disorder After the SARS Epidemic

Source	Time After Epidemic	Psychiatric Disorder
Lee et al. 2007[154]	1 year	64%
Mak et al. 2009[155]	30 months	33.3%
Lam et al. 2009[156]	4 years	42.5%

5.2.6 Economic Burden

The SARS epidemic is estimated to have cost anywhere from $30 to $100 billion worldwide from treatment costs, productivity loss, and decrease in travel and tourism.[157] Some estimates place the economic burden at US $30 billion in the Far East alone.[158] This burden translated into a decrease in Gross Domestic Product (GDP) for many countries. Hong Kong experienced the greatest loss, with a 2.63% decline in GDP, while China's GDP fell 1.05%. GDP in United States fell 0.07%.[159] While the percentages may appear small, Table 5.5 shows the estimated economic loss in US dollars resulting from the epidemic.

Source	**Region**	**Economic Loss**
Mackenzie et al. 2013[160]	Worldwide	$40 billion
Lee et al. 2004[161]	Worldwide	$40- $54 billion
Wen et al. 2004[162]	China	$25.3 billion
Siu et al. 2004[163]	China	$48 billion
Fan 2003[164]	East & Southeast Asia	$12.3- $28.4 billion

On May 18, 2004, the WHO declared the last SARS case to be contained. No human infections have been reported since due to the stringent disease control and public health response.[165]

5.3 Middle East Respiratory Syndrome

5.3.1 Summary

- Outbreaks of MERS were first identified in 2012 and have occurred sporadically since that time,
- To date these outbreaks have led to more than 1,000 cases and nearly 500 deaths, the burden of which fell disproportionately on the elderly with significant co-morbidities, and
- The vast majority of cases have been identified in the Middle East, and, recently South Korea although cases have been identified sporadically in countries in Europe and North America.

5.3.2 Background

Middle East Respiratory Syndrome (MERS) is an acute severe respiratory infection of zoonotic origin caused by a corona virus knows as MERS-CoV. Although the natural source is unconfirmed, MERS-CoV has been identified in camels in the Arabian Peninsula. MERS transmission has occurred through close contact between humans and animals, most likely dromedary camels or bats.[166] Both the MERS-CoV virus and its antibodies have been isolated in dromedary camels in the Arabian Peninsula. These findings reinforce the possibility of camel-to-human transmission through close contact and the ingestion of raw camel milk. While camel meat could also be a source of infection, cooking the meat is customary and inactivates the virus.[167]

Patients display symptoms such as fever, cough, shortness of breath, sore throat, and myalgia; some infected people show no symptoms at all. Approximately three to four out of every ten persons suspected of MERS have died. Most fatalities, however, had significant co-morbidities that exacerbated the MERS symptoms.[168]

5.3.3 The Emergence of MERS

The first MERS case was reported in Saudi Arabia in September 2012. From September 2012 to July 2015, 1,368 laboratory-confirmed cases have been reported to the World Health Organization (WHO), at least 487 of which resulted in death. A total of 26 countries in the Middle East, Africa, Europe, Asia, and North America have had at least one MERS case. Approximately 75% of cases, however, have been from Saudi Arabia. All cases have been directly or indirectly linked to the Middle East. The United States has only had two cases, both in travelers.[169] This information can be seen in Figure 5.4 below from the WHO.

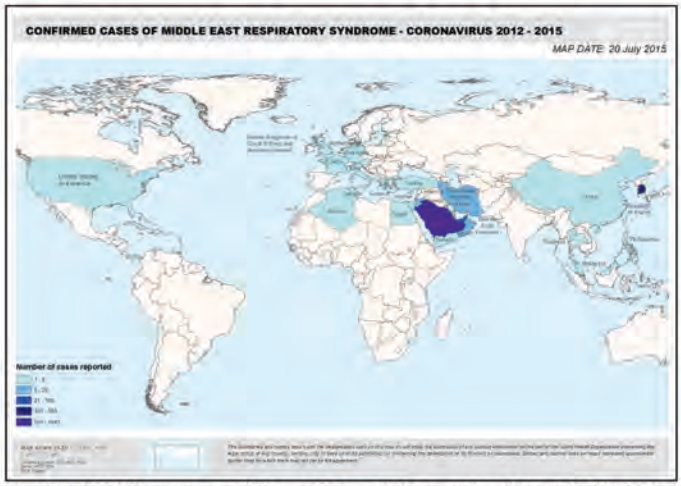

Figure 5.4. Confirmed MERS cases around the world since 2012, reproduced from The World Health Organization, Summary of Current Situation.[170]

5.3.4 Morbidity and Mortality

The overall MERS case fatality rate is almost 40%.[171] The WHO reported the median age of SARS cases to be 50 years old, with a range from nine months to 99 years.[172] One study of MERS patients in Saudi Arabia found a clear relation between case fatality rates and increasing age. The data supporting this correlation is provided in Table 5.6 below.[173]

Table 5.6. Case Fatality Rates with Increasing Age[174]

Age	Case fatality rate
< 19 years	0%
< 50 years	39%
< 60 years	48%
> 60 years	75%

Studies have also found that a large proportion of MERS cases are in patients with underlying medical conditions, such as diabetes and hypertension as well as chronic renal, lung, and cardiac disease (Table 5.7).[175]

Table 5.7. Percent of MERS Patients with Underlying Medical Conditions

Source	Percent with Comorbidity
Penttinen et al. 2013[176]	73%
Assiri et al. 2013[177]	96%
Arabi et al. 2014[178]	100%

Although the disease may have existed for some time before detection, MERS is a relatively new communicable disease. Research on long-term morbidity, mortality, and economic burden of the illness is in progress as the epidemic itself is still ongoing. Cases have been localized mostly to the Middle East, although cases occurred in China, Thailand, the Philippines, and the Republic of Korea in the spring and summer months of 2015.

5.3.5 2015 Outbreak

As of the writing of this section (summer of 2015), the Republic of Korea is currently experiencing the largest known MERS outbreak outside of the Arabian Peninsula. In May 2015, an infected traveler returned from the Middle East with MERS. His travel history went unreported for over a week, openly exposing many people to the virus. [179] Since then, there have been 186 confirmed cases of MERS—185 in the Republic of Korea and one in China—of which the median age is 55 years old.[180] There have been 36 deaths reported; 91.7% of the deaths were in the elderly or patients with co-morbidities. Approximately 17,000 people were quarantined.[181]

The Republic of Korea's cultural traditions are said to have influenced the rapid transmission of MERS within the country. Customs encourage friends and family to not only visit ill patients, but provide extensive bedside care. Further, in Korea, patients tend to visit several medical facilities before admitting themselves. These dispositions increase exposure and transmission of the virus.[182] It is not surprising therefore that all of the cases in Korea have been associated with health care facilities; 14% were in medical professionals. Every patient has been connected to the index case and no cases have occurred in the general population.[183] The last MERS case was reported to the WHO on July 4, 2015 and officials believe the outbreak to under control in China and the Republic of Korea. Cases continue to be reported, however, in the Arabian Peninsula.[184]

5.4 Influenza

5.4.1 Summary

- Influenza viruses cause human outbreaks seasonally, in pandemics and via zoonotic infection from birds,
- Morbidity and mortality from influenza is difficult to measure because death is due to secondary causes,
- Five to ten percent of the population worldwide gets influenza every year, and it is associated with 250,000-500,000 deaths annually, the burden of which falls mostly on the elderly,
- Seasonal influenza causes approximately $100Bn in direct and indirect economic losses in the US annually,
- Pandemic strains have caused a handful of outbreaks in the last 100 years, and are sometimes associated with significantly more illness or deaths than seasonal strains,

- Pandemic strains have been noted for disproportionally harming groups other than the elderly (young adults for the 1918 pandemic and young children for the 1957 and 2009 pandemics),
- Deaths from pandemics and seasonal influenza decreased across the 20th century until the 1960s, after which time the death rate from influenza has remained relatively constant,
- Outbreaks of avian influenza have caused up to $20B in direct and indirect economic losses due to destruction of poultry flocks and lost trade,
- Avian influenza outbreaks have an unpredictable effect on human health, the worst are associated with up to 1,000 cases and 500 deaths, some cause mild illness in humans, and
- Vaccines and antivirals demonstrate significant efficacy in clinical trials, however their overall public health benefit is more difficult to measure.

5.4.2 Background

Influenza is a highly contagious viral infection of the respiratory tract caused by three orthomyxoviruses of different antigenic types —influenza A, B, and C. These influenza viruses can cause seasonal and pandemic outbreaks. According to the CDC, an influenza pandemic "can occur when a non-human (novel) influenza virus gains the ability for efficient and sustained human-to-human transmission and then spreads globally." Seasonal outbreaks, however, occur annually on predictable seasonal patterns and are caused by recirculating influenza viruses with residual immunity among the population. Both seasonal and pandemic outbreaks spread through human-to-human transmission. Sporadically, avian influenza viruses, which do not normally infect or transmit through humans, will cross species barriers and cause an outbreak in the human population.[185]

Influenza type A can infect a variety of animal hosts and is further divided into subgroups based on its surface proteins (e.g., H1N1, H3N2, H5N1). This genetic variation allows type A viruses to cause pandemic outbreaks, dominate seasonal epidemics, and cross species barriers.[186] Type B viruses have a more limited host range and limited variation, and therefore, do not cause pandemic outbreaks. Virus type C causes only mild symptoms in humans and does not contribute to epidemics.[187] Influenza virus is consistently one of the leading causes of illness in the United States and is associated with significant mortality; it is among the US Centers for Disease Control and Prevention's (CDC) top priorities.[188]

5.4.3 Seasonal Influenza

Seasonal influenza viruses circulate through the population causing annual epidemics during the winter months in temperate climates, such as the United States, and unpredictable epidemics in tropical regions. The World Health Organization (WHO) estimates that 5%-10% of adults and 20%-30% of children

worldwide are infected with influenza each year. Of those illnesses, three to five million develop into severe cases, which result in 250,000 to 500,000 deaths annually.[189]

5.4.4 Morbidity and Mortality of Seasonal Influenza

In developed countries, approximately 1.2 in 10,000 persons die annually as a result of influenza.[190] Industrialized countries with established surveillance systems provide the majority of case data so these attack rates could be substantially underestimated for developing, tropical countries with limited financial and technical resources.[191] Globally, influenza drives the loss of 19.2 million disability-adjusted life years (DALYs) annually (16.9 million-21.5 million), as estimated in the Global Burden of Disease Study in 2010. This statistic is equivalent to 279 DALYs (245-311 DALYs) per 100,000 people worldwide.[192]

According to the National Strategy for Pandemic Influenza by the Homeland Security Council, an average of over 200,000 hospitalizations and 36,000 deaths are caused each year by seasonal influenza in the US alone.[193] Anywhere from 5-20% of the population, or 15 to 60 million Americans, is infected with the influenza virus annually.[194] Death tolls range from 1.4 to 16.7 deaths per 100,000 persons, exceeding a total of 49,000 lives.[195] A CDC study estimated that, since the 1980s, the hospitalization rate has ranged from 150,000 to 431,000 people per year.[196] Seasonal influenza is consistently ranked in the top ten overall leading causes of death in the United States.[197] After convalescence, however, no long term morbidities are associated with influenza.[198]

5.4.5 Uncertainty When Determining Influenza-Associated Morbidity and Mortality

The CDC is uncertain on exactly how many people become infected with or die from influenza each year. States are required to report influenza-related deaths in children under 18 years old only, leaving all other cases and deaths untracked. Seasonal influenza is rarely listed as a cause of death on adults' death certificates. Additionally, death often occurs weeks after initial infection when patients are no longer symptomatic and the virus cannot be detected. Some diagnostic tests can even produce false negative results due to their low sensitivity.[199] For these reasons, the CDC must estimate the number of annual cases and deaths caused by influenza. The estimate is typically based on deaths related to pneumonia and influenza (P&I) to account for the fact that although influenza is never confirmed as the cause of death, pneumonia is most often the underlying cause.[200] Excess P&I deaths, however, only account for approximately 25% of actual influenza-related mortality.

200 World Health Organization (2005) Influenza Vaccines. *WHO Position Paper* 33: 279-287

One estimation method for influenza deaths is excess mortality, which is the difference between mortality rates during an influenza epidemic and the standard baseline rate in the absence of an influenza outbreak. While there is never a total absence of influenza illness, comparing the rate of illness during a predictable seasonal outbreak to the baseline rate during the summer months when there is no outbreak provides an estimation for the illnesses being caused by the outbreak. For example, during the 2013– 2014 influenza season the percentage of deaths attributed to P&I peaked at 8.7%. The baseline rate of P&I related deaths that occur during a non-outbreak time period, however, was about 7% and hence, the difference of 1.7% of P&I related deaths can be attributed to the seasonal influenza outbreak.[201]

The excess index can also be applied to the number of outpatient visits to evaluate excess morbidity.[202] The national baseline for the percentage of outpatient visits is the mean percentage of P&I visits during non-outbreak weeks for the previous three seasons plus two standard deviations and is usually about 2.0%. The baseline for mortality is calculated using a periodic regression model applied to data from the previous five years. It ranges from 6-8%, but is usually around 7.5% during seasonal influenza months.[203] Excess morbidity and mortality are not intended to provide exact statistics, but serve as an indicator of the season's relative severity. Hospitalization rates are not reported as an excess index, but instead as laboratory-confirmed statistics.

5.4.6 Consequences in Special Populations

Influenza harms young children and the elderly more than older children and non-elderly adults. The WHO reports that excess mortality attributed to influenza ranges from three to 15 per 10,000 Americans older than 65 years. In the general population, excess morbidity is approximately 1.2 in 10,000 persons per year.[204] Excess hospitalization averages at 100 per 10,000 for children under six months old, but only four per 10,000 children once they are more than five years old.[205] Persons in the age group from five to 49 years have the lowest hospitalization rate.[206]

Seasonal influenza disproportionally kills the elderly, who suffer approximately 80-90% of the mortality observed.[207] This trend is evident in Figure 5.5, from a CDC sponsored study on the epidemiology of seasonal influenza, giving both hospitalization and mortality rates.

Influenza cases typically resolve within two weeks, however severe cases or cases in elderly or at-risk populations may lead to additional complications. Complications include pneumonia, bronchitis, and exacerbation of existing pulmonary and respiratory diseases and could lead to death. Resolved cases, however, are not associated with long-term morbidity.[208]

5.4.7 Influence of Influenza Virus Type

Since 1968, influenza A, both H1N1 and H3N2, and influenza B have all co-circulated to cause seasonal epidemics. Seasons dominated by influenza A H3N2 tend to cause greater excess mortality than influenza A H1N1 and B seasons.[216] From 1990-1999, overall influenza-related mortality ranged from 17,000 to 51,000 deaths in a season. Around 90% of seasons were predominated by H3N2 strains and thus, influenza-associated mortality rose during that time compared to an average year. The increase, however, can also be partly associated with the large proportion of the population that was over 65 years old and tend to suffer more from influenza infections.[217]

5.4.8 Recent Influenza Seasons

In the past decade, both seasonal and pandemic strains have caused fluctuating outbreaks, as can be seen in Figure 5.6 and Figure 5.7 below. From 2007– 2008, the H3N2 seasonal virus predominated in the United States. That season saw the greatest mortality and hospitalization rates of the previous four years, at 83 deaths of children under four years old. The percentage of the population with P&I related deaths peaked at 9.1%, which is well above the normal baseline of 7.6%.[218]

The following influenza season, from 2008– 2009, was less severe and can be attributed to the H1N1 dominant strain that typically causes more mild outbreaks. There were only 45 pediatric deaths and a hospitalization rate of 2.8 per 10,000 children. Outpatient visits peaked at 3.7%, well over the baseline of 2%, and the weekly percentage of deaths attributed to P&I peaked at 7.6%, which is at the baseline of 7.6%.[219]

A pandemic virus emerged the following year. The 2009 H1N1 pandemic strain was unusually severe, causing an extended outbreak from April 2009 through May 2010. Infections persisted through the summer months, speaking to the strain's augmented pathogenicity and transmissibility. Excess mortality peaked at 8.1% in November and again at 8.2% in January, exceeding the national baseline for thirteen weeks straight. The pandemic resulted in the greatest number of patient visits of any year since influenza surveillance began in 1997.[220] Seasonal influenza typically burdens the elderly population the most with 80-90% of the mortality. This pandemic, however, affected children and young adults much more substantially. An estimated 80% of deaths were in people under 65 years old.[221] There were 344 reported pediatric deaths.[222]

By the 2010– 2011 season, the pandemic H1N1 strain continued to circulate. The H3N2 strain and influenza B were also widely distributed, resulting in a more balanced attack rate among all age groups. The season was significantly less severe than the previous pandemic year, but still worse than the

previous 2008– 2009 endemic. There were 105 confirmed pediatric deaths. Outpatient visits peaked at 4.6%, the hospitalization rate was 4.38 per 10,000 children, and excess mortality surpassed the epidemic threshold for 13 consecutive weeks, peaking at 8.9%.[223]

Once again in the 2011– 2012 season, all three strains—H1N1, H3N2, and type B— circulated, but H3N2 was the predominant virus. This mild season was noted for lower hospitalization rates, outpatient visits, and deaths than previous years. The hospitalization rate amounted to only 0.86 per 10,000 people and patient visits dropped to the lowest since point 1997 by meeting, but not exceeding the threshold baseline of 2.4%. The P&I associated death rate surpassed the baseline for one short week, at 7.9%, and only 26 pediatric deaths were reported.[224]

The 2012– 2013 epidemic was more severe. All three virus types circulated, but H3N2 was the main circulating virus. Patient visits soared past endemic thresholds for 15 weeks at a high of 6.1%, much greater than the national baseline of 2%, and hospitalization rates escalated to 4.43 per 10,000 people. Mortality also surpassed the baseline for 13 weeks, reaching 9.9%. There were 149 influenza-associated pediatric deaths.[225]

From 2013– 2014, the pandemic influenza A H1N1 strain co-circulated with limited H3N3 and B strains. This was the first season since 2009 that the pandemic strain predominantly recirculated, this time as a seasonal virus. Although there were fewer deaths and hospitalizations than typically observed with an H1N1 season, adults were once again at a higher-risk for influenza. Those aged 50-64 experienced 5.43 hospitalizations per 10,000 persons compared to the aggregate rate of 3.56 per 10,000 across all age groups. Outpatient visits exceeded the baseline for 15 consecutive weeks, peaking at 4.6%, and excess mortality exceeded for eight weeks, maxing out at 8.7%. There were 96 pediatric deaths reported.[226]

Table 5.10 below compiles key CDC statistics from the Emerging Infections Program (EIP) for recent influenza seasons in the United States. Beginning in 2009, EIP was expanded to surveille 26 million more Americans, 8.5% of the population.[227] This new FluSurv-NET program may account for some of the differences in comparable statistics.

5.4.9 Economic Burden of Seasonal Influenza

The US public health infrastructure is burdened with 24.7 million (19.9-30.1 million) cases of seasonal influenza annually. These cases generate approximately 31.4 million (22.6-43.5 million) outpatient visits

[235] Ibid.
[236] Ibid.

and 3.1 million days of hospitalization, producing approximately a $10.4 billion ($4.1- $22.2 billion) burden of direct medical costs from annual influenza endemics, according to a 2003 study by the Immunization Service Division and Division of Viral Diseases at the CDC.[237] Additionally, anywhere from $8.7 to $31 billion in earnings is lost annually due to decreases in productivity and loss of life from the estimated 610,000 (360,000- 953,000) DALYs lost. In total, the annual costs of seasonal influenza amount to $87.1 billion ($47.2- $149.5 billion) in direct and indirect costs in the United States.[238] Table 5.11 below displays several studies' estimated economic harm of seasonal influenza on the US. Echoing these data, the WHO reported that France and Germany may spend anywhere from $1 million to $6 million per 100,000 people annually on influenza outbreaks.[239]

Table 5.11. Studies on the Direct Medical Cost and Total Economic Burden of Seasonal Influenza Annually on the US

Source	Medical Costs (per year)	Economic Burden (per year)
Office of Technology Assessment 1981[240]	$1- $3 billion	-
Molinari et al. 2007[241]	$10.4 billion	$87.1 billion
Mao et al. 2012[242]	$10.3 billion	$29.1 billion

5.4.10 Pandemic Influenza

In addition to the annual burden of seasonal influenza, several pandemic strains have caused additional morbidity and mortality over the past century. Over the past 300 years, ten pandemics are known to have occurred, three of which were in the 20th century.[243]

The 1918 influenza pandemic, also known as the "Spanish Flu" (the exact location of origin was never determined), was the deadliest outbreak in modern history.[244] The H1N1 outbreak occurred in three waves beginning in March 1918. The second and most severe wave occurred concurrently in North America, Africa, and Europe in August 1918.[245] Over the next six months, anywhere from 20-40% of the global population was infected with influenza and approximately 500 million people became ill.[246] Estimates on the total mortality ranges from 20 to 100 million worldwide, but most estimates suggest approximately 50

million deaths.[247, 248] In the United States, between 550,000 and 675,000 deaths were attributed to the pandemic.[249, 250]

Unlike seasonal influenza, the highest rates of morbidity and mortality were observed in young, healthy adults instead of the elderly.[251] The case fatality rate was greater than 2.5%, compared to later pandemics that were less than 0.1%.[252] The reason for the severity of the outbreak is unclear, considering the attack rate and age distribution was similar to other pandemics. Moreover, H1N1 outbreaks are typically associated with lower levels of morbidity and mortality.[253] In total, anywhere from 1% to 3% of the global population died as a result of this pandemic.[254]

In February 1957 another pandemic strain emerged, influenza A H2N2 originating from China. The virus spread rapidly around the world and to the United States, with most related excess mortality occurring between September 1957 and March 1958.[255] Morbidity in children exceeded 50%.[256] Approximately 70,000 deaths occurred in the United States and two million worldwide, which amounts to approximately 0.07% of the population worldwide dying from influenza-associated causes.[257]

Just over a decade later, a new influenza A H3N2 strain emerged in Hong Kong in July 1968. The virus was slow moving, it didn't reach the United States until December and Europe the following year.[258] Attack rates peaked at 40% in children, but mortality rates were highest in the elderly. The excess mortality amounted to approximately 33,800 deaths in the United States, mild for a pandemic outbreak.[259] The 1968-1969 outbreak had the lowest mortality rate of any other pandemic of the century, possibly due to partial immunity from exposure to the 1957 pandemic strain and improved medical treatment.[260] Overall, approximately 0.03% of the population worldwide died from influenza-associated causes during the 1968 pandemic.[261]

Table 5.12 below presents the age distribution of mortality attributable to influenza during 20th century influenza pandemics. Figure 5.8 shows antigenic type and associated age-based mortality of pandemics through 1995. Interpandemic seasons are also included for comparison.

Table 5.12. Influenza-Associated Mortality (per 100,000) Across Age Groups During Pandemics in the US [262]

Season	Pandemic Strain	All ages	< 65 years	≥ 65 years
1918-1919	H1N1	529	546	166
1957-1958	H2N2	39	15	273
1968-1969	H3N2	8.1	4.3	44

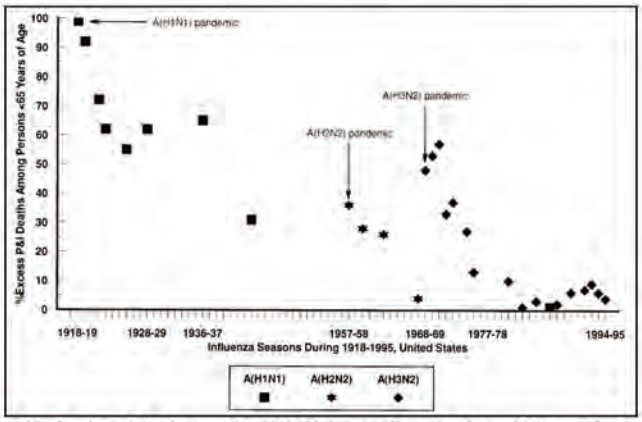

Figure 5.8. Age distribution of deaths associated with influenza A pandemics and interpandemic seasons in the United States, 1918-1995, reproduced from Simonsen et. al[263]

In 2009, a pandemic H1N1 strain quickly circulated through 74 countries during the summer months, an unusual time for the virus.[264] The excess mortality is estimated between 152,000 and 575,000 people worldwide. Populations in Africa and Asia suffered approximately 50% of the deaths, possibly due to the limited availability of medical treatment, presence of underlying health conditions, lower qualities of care, and fragile nutritional status.[265] In the initial stages of the pandemic, Mexico was spending an estimated $57 million per day trying to control and treat the virus. The World Bank claimed a total $3 trillion loss from the burden of the pandemic.[266]

In the United States, from 43 to 89 million people became infected with pandemic H1N1, resulting in 9,000 to 18,300 deaths. Point of care testing used to identify the virus is less sensitive on pandemic strains

266 Lagace-Wiens PR *et al* (2010) Influenza epidemiology--past, present, and future. *Crit Care Med* 38: 1-9

and therefore, infection rates also could have been much greater.[267] Children experienced significantly higher mortality and hospitalization rates than the elderly, who are normally the most affected population group, as can be seen in Table 5.13. The hospitalization rate was 8.3 per 10,000 among ages zero to four years and 3.4 per 10,000 among ages 5-17 years while only 3.2 per 10,000 for those over 65 years.[268] The severity and extent of the outbreak was curtailed by the rapid vaccination of more than 80 million people. The H1N1 pandemic strain continues to circulate today as a seasonal human flu virus.

Table 5.13. Statistics on the Number of Influenza Cases, Influenza-Related Mortality, and Hospitalization Rate Resulting from the 2009 H1N1 Pandemic in the US

Season	Case Count	Death Toll	Hospitalization Rate (per 10,000 persons)		
			< 4 years	5-17 years	> 65 years
2009	43-89 million	9,000-18,000	8.3	3.4	3.2

5.4.11 Pandemic Threats

Over the past century, there were also several instances of newly emerged influenza strains that were feared to cause a pandemic but did not. In 1976, a swine strain with similarities to the 1918 pandemic strain emerged at Fort Dix, New Jersey. Due to a robust vaccination campaign and other unknown factors, the virus never became widespread. Then again in May of 1977, a new virus type surfaced in China and began to rapidly spread around the world. The strain was similar to strains circulating prior to 1957. Many adults had already developed immunity to the virus, which limited outbreaks to children mainly and prevented a major pandemic. Decades later in 1997, once again in China, a novel H5N1 virus began to infect young adults directly from chickens. Over one million chickens were culled to successfully prevent further spread of the avian flu.[269]

5.4.12 Avian Influenza

Within the past two decades, avian influenza A has caused substantial morbidity and mortality in humans. Of the many existing strains, H5 and H7 subtypes have been the primary transmission sources from birds to humans. H5N1 viruses are endemic in Asia and Africa while subtype H7 circulates across Europe and North America.[270] Avian influenza A viruses are either highly pathogenic (HPAI) or have low pathogenicity (LPAI) based on the degree of infection caused by their molecular characteristics. While bird-to-human transmission of avian influenza is a persistent issue, sustained human-to-human transmission of avian strains has not been observed.[271]

The H5N1 virus first infected humans in Hong Kong in 1997 stemming from an outbreak in poultry. It reemerged in mainland China in 2003 and quickly spread through wild bird migration and domestic poultry trading among Asia, Africa, and Europe. The virus remains endemic in birds, with sporadic

transmission to humans.[272] These H5N1 viruses had various genotypes of geographically-related sublineages. [273] Since reemerging in 2003, and up to July 2015, there have been 844 cases of human infection with H5N1 and 449 deaths reported to the WHO, equating to a 53% mortality rate (Figure 5.9). Sixteen countries have had outbreaks of H5N1 avian influenza; Egypt, Indonesia, and Viet Nam have experienced the most cases.[274]

H5N1 was the first avian influenza virus to continuously circulate in Asia for over 16 years.[275] According to the Food and Agriculture Organization of the United Nations, by 2008 the economic losses were estimated to have already reached $20 billion worldwide. The two US outbreaks were estimated to have cost $65 and $140 million from the loss of poultry and cost of disease control alone. The United States also committed $1.4 billion towards the international effort against H5N1.[276] The economies of countries in East and Southeast Asia suffered the most due to the affect H5N1 had on the poultry industry. From 2003 to 2005, an estimated ten billion dollars was lost from the death or culling of over 140 million birds in Southeast Asia. GDP was depleted by 0.6% to 2% among affected countries.[277]

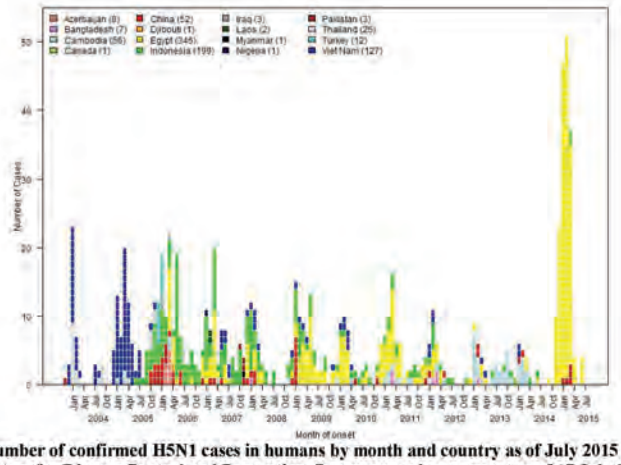

Figure 5.9. Number of confirmed H5N1 cases in humans by month and country as of July 2015 reproduced from The Centers for Disease Control and Prevention, Summary and assessment as of 17 July 2015.[278]

In March 2013, the H7N9 virus was identified as the causative agent of infections in two patients in Shanghai and one in Anhui Province, China. Spread throughout China continued through exposure to

infected birds, typically in live poultry markets, but not through human-to-human contact.[279] As of July 2015, 677 cases of H7N9 with at least 275 deaths have been reported to the WHO, a 41% mortality rate (Figure 5.10). The virus remains endemic in China, but no cases have been reported outside of the mainland.[280] According to the United Nations, China experienced over $6.5 billion in losses from the H7N9 outbreak.[281]

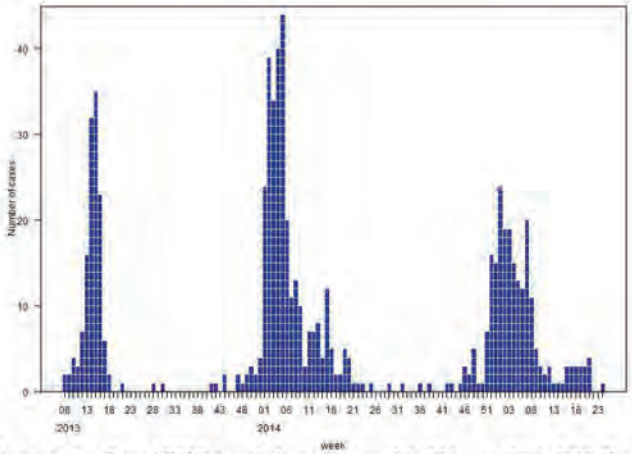

Figure 5.10. Number of confirmed H7N9 cases in humans by week in China as of July 2015. Figure reproduced from The World Health Organization, Summary and assessment as of 17 July 2015.[282]

Since 2002, other influenza H7 subtypes have caused more than 100 human infections. Subtype H7N2 caused a widespread outbreak on domestic turkey farms in the northeastern United States in 2002. One worker in Virginia became infected with the virus while birds were being culled to contain the outbreak, which proved the possibility of bird to human transmissibility in the US. A year later in New York, H7N2 was identified in an immunocompromised man who denied contact with any live poultry.[283] The transmission source remains unknown.[284] Both US cases of human H7N2 fully recovered. In the United Kingdom, several cases of H7N2 were reported in 2007; three people were hospitalized, all of whom recovered.[285]

Human H7N3 has been identified in Italian poultry workers in 2003, Canadian poultry workers in 2004, and one poultry worker in the United Kingdom in 2006.[286,287,288] Years later in 2012, H7N3 caused a severe outbreak in chicken farms in Mexico that resulted in two infected workers. While H7N3 is capable of human infection, few cases and no deaths have been reported; the subtype's capability within humans appears limited.[289]

The first emergence of H7N7 was in 1996 when a woman became ill after cleaning her poultry shed in England.[290] Then in 2002, a H7N7 outbreak in the Netherlands became the first avian influenza outbreak in humans since H5N1 emerged. A poultry outbreak on commercial farms led to more than 1000 people with subclinical indications, 86 human infections, and at least one death.[291] During an outbreak in Italy in 2013, three poultry workers contracted H7N7 without respiratory symptoms. Human to human transmission did not occur.[292] Transmissibility of the H7N7 strain is still not well understood.

5.4.13 Trends in Mortality from Influenza in the 20th Century

Unlike the newly emergent diseases SARS and MERS, influenza has caused human misery for centuries. Because of the lack of historical data as well as the difficulty of determining influenza mortality as previously described, little research exists on the historical trends of influenza. As discussed above (and shown in Figure 5.12), although Simonsen et al. focused on pandemic influenza, their data on mortality from intrapandemic seasons shows an overall downward trend in mortality from seasonal influenza.[293] Doshi et al. used mortality reports from *Vital Statistics of the United States* along with US Census estimates to calculate the incidence of influenza mortality over the past century during pandemic and seasonal outbreaks (Figure 5.11).[294] The *Health Sentinel* also analyzed mortality reports from *Vital Statistics of the United States* along with other statistics from the HHS to determine the incidence of influenza mortality over the past century (Figure 5.12).[295] Although both groups likely capture deaths from respiratory ailments other than influenza, both groups show a significant reduction in annual deaths from influenza. Importantly, although both papers suggest an overall drop in mortality over the past hundred years, both papers also clearly show that the downward trend has largely ceased, as mortality from influenza has been roughly the same in the last thirty years (and perhaps over the last 50). Without significant medical advances in the future, we can expect seasonal influenza to kill tens of thousands of Americans and nearly half a million people globally every year.

5.4.14 Medical Countermeasures Against Influenza

Medical countermeasures (MCM) are crucial for both preparedness and response to influenza. There are two main types of influenza countermeasures: antiviral agents and vaccinations. Research on development of an influenza vaccine began soon after the virus was isolated in 1933.[298] The first wide-scale use of the vaccine occurred in 1945 during World War II among the US military. In 1960, after the 1957-1958 pandemic, the US Surgeon General recommended influenza vaccinations for high risk groups, including the elderly, pregnant women, and those with chronic conditions. Then in 2010, after the 2009 H1N1 pandemic, the Advisory Committee on Immunization Practices promoted universal influenza vaccination in persons over six months for the first time.[299]

Adamantanes and neuraminidase inhibitors are the two classes of antiviral drugs approved by the Food and Drug Administration (FDA) for use against influenza. The adamantanes, amantadine and rimantadine, are agents against influenza A and were approved for treatment in the 1966 and 1973, respectively. The Centers for Disease Control and Prevention (CDC) no longer recommends adamantanes for the treatment of seasonal influenza due to increasing resistance of circulating strains.[300] The

neuraminidase inhibitors, oseltamivir and zanamivir were both approved in 1999 and function against influenza A and B.[301] Peramivir, also a neuraminidase inhibitor, was recently approved in December 2015.[302]

5.4.14.1 Efficacy

Seasonal influenza and pandemic influenza respond differently to the available MCM. This section summarizes the efficacy of the currently available MCM. Additional details and references are provided in the Supplemental Information.

5.4.14.2 Seasonal Influenza

Antivirals

There are two categories of influenza antiviral drugs, but because adamantanes are no longer recommended for treatment of seasonal influenza, they are not considered in this analysis.[303]

There are three neuraminidase inhibitors used to treat seasonal influenza: oseltamivir, zanamivir, and peramivir. Antiviral treatment is most effective when administered within 48 hours of symptom onset.[304] Antivirals can have a variety of benefits for patients suffering from seasonal influenza (see Supplemental Information on Antiviral and Vaccine Efficacy):

- Duration of symptoms is decreased by 15-40%,
- Reduction of the probability of death from influenza by five-fold, and
- Reduction in the amount of viral titer and the duration of viral shedding by 25-70%.

Antivirals can be provided as prophylaxis as well. If provided prior to exposure, antivirals prevent symptoms of seasonal influenza in 80% of patients.

Vaccines

Based on the CDC's reported adjusted overall vaccine effectiveness (the reduction in risk of needing a doctor's visit) for influenza seasons from 2005– 2015 (excluding the 2008– 2009 influenza season), the weighted average of vaccine effectiveness for seasonal influenza is 44.2%.[305] Seasonal influenza vaccination is also effective in preventing severe influenza. Each year, on average, vaccination produces, a 15% reduction in hospitalizations due to influenza illness. This result agrees with more recent studies that also show less than a 50% efficacy.[306]

One study suggests that a previous year's influenza vaccine may confer protection against current circulating viruses. During the 2012–2013 season, the vaccine effectiveness against influenza A (H3N2)

among people who received the 2012– 2013 vaccination was similar to those who received only the 2011– 2012 vaccination.[307]

5.4.14.3 Pandemic H1N1 Influenza

Antivirals

During the outbreak of pandemic H1N1 influenza, most patients were treated with oseltamivir, based on the CDC's recommendation. Of the 3,362 2009 pandemic influenza A (H1N1) virus isolates collected, only three did not show resistance to adamantanes.[308] Patients that received oseltamivir treatment had a survival rate of 90.3%, and antiviral treatment was associated with a 20% reduced mortality risk when compared to no treatment.[309] In addition, patients receiving early oseltamivir treatment had shorter fever durations than patients who did not receive antiviral treatment.[310,311]

Antiviral treatment is also effective in reducing viral titer and duration of viral shedding in pH1N1 patients. According to one study, antiviral treatment reduced the mean viral load of patients by 14.3%.[312] On average, antiviral treatment reduced the duration of viral shedding in patients by 34% when compared to untreated patients or patients who received antiviral treatment after 48 hours, which has been shown to be less effective.[313]

A study in ferrets showed that prophylaxis with oseltamivir did not prevent H1N1 infection.[314] However, a household contact study showed that contacts under 20 years old who received antiviral prophylaxis with oseltamivir or zanamivir were nearly seven-fold less likely to be infected with pandemic H1N1 influenza than those who did not receive antiviral prophylaxis (odds ratio 0.15).[315] Additionally, other observational studies indicate that prophylaxis may be effective in preventing H1N1 infection.[316,317]

Vaccines

Monovalent pH1N1 influenza vaccine demonstrated an average effectiveness of 66% (range 60-93%).[318,319]

5.4.14.4 Epidemiological Evidence of Effectiveness

The previous section describes the efficacy of vaccination in controlled, clinical trials. The epidemiological evidence is equivocal.

Supporting the benefit of vaccination, the Influenza Division at the CDC released a study on the mortality of the nine influenza seasons from 2005 to 2014. Their analysis found that approximately 22% of influenza-associated deaths were prevented by the influenza vaccine, with 90% of this benefit realized in persons over 65 years.[320] Further, they conservatively estimated 40,000 deaths to have been averted. The study found that the fewest deaths were prevented during the 2009– 2010 pandemic.[321] Another CDC study found that from 2005 to 2011, influenza-associated illnesses and hospitalizations were substantially alleviated by vaccinations. The analysis estimated that 1.1 to five million illnesses and 7,700 to 40,400 hospitalizations were prevented in those vaccinated against influenza. The study also found the largest benefit to be in elderly populations.[322]

Other studies found less favorable outcomes. Demicheli et al. presented a meta-analysis that showed poor effectiveness of the vaccine in reducing influenza cases and work days lost in healthy adults. The study did find, however, significant reductions in serologically confirmed cases of influenza.[323] According to the National Center for Health Statistics, while vaccination coverage spanned 15-20% of the elderly population by 1980 and increased to 65% in 2001, influenza-associated mortality substantially increased among those over 65 years old.[324] Likewise, a retrospective analysis covering the years 1979 to 2000 from The Institute for Chronic Illnesses found the vaccine to have little or no effectiveness for preventing influenza cases, deaths, or hospital admissions.[325] Simonsen et al. at the National Institute of Allergy and Infectious Diseases published that based on national vital statistics, other studies on the effectiveness of the influenza vaccine overestimate its benefits.[326] Despite increasing vaccination coverage from 1970 to 2001, Rizzo et al. found no evidence of a reduction in influenza-related morality in the Italian elderly population.[327] Several research groups propose that the overestimate of vaccine benefits is due to unrecognized confounding variables, such as a disproportionate amount of healthy elderly persons being

vaccinated.[328] Moreover, Madea et al., did not find significantly different levels of infection between vaccinated and unvaccinated healthy children six to 24 months of age.[329]

Regardless of differing opinions on vaccine efficacy, the decline in influenza morbidity and mortality over the past century is irrefutable. As Doshi et al. highlights, however, influenza vaccination was not available until the 1940s and not widely adopted until the 1980s and hence cannot be responsible for the drop (see Figures 5.11 and 5.12 above).[330]

Few studies exist on the relationship between influenza countermeasures and the decreases observed in morbidity and mortality, however the advent of antibiotics likely significantly reduced risk of death from influenza. In the absence of antibiotics, the majority of influenza mortality is attributed to interactions between the influenza virus and bacteria colonizing the upper respiratory tract, causing fatal secondary infections.[331] Evidence strongly suggests that the 1918 pandemic would have been greatly mitigated with the availability of antibiotics.[332]

5.4.14.5 Availability of Vaccines

Vaccine shortages have captured headlines several times over the past couple decades for various reasons, including underestimation of demand, reduction in manufacturers, contaminated issues, and unexpected outbreaks.[333] After the severe influenza vaccine shortages of the 2004 to 2005 season, the United States Government Accountability Office completed a study on the status of seasonal influenza preparation. The final report recognized that the vaccine shortage of 4.7 million doses, approximately half of the needed supply, exposed the need for better preparation for seasonal endemics.[334] During the 2009 H1N1 pandemic, experts predicted 160 million doses of the pandemic vaccine would be available for public vaccination by October, yet only 30 million were delivered by that date.[335]

6 Risk Assessment of Laboratory Accidents and Natural Disasters

6.1 Overview of Results

The Biosafety Risk Assessment evaluated the increase in risk to human health of pandemics caused by modified strains of the influenza viruses and the coronaviruses. In every case, the increase in risk compared to wild type strains was provided to determine if GoF experiments could create pathogens that are *more likely* to cause laboratory acquired infections, *more likely* to create a local outbreak, or *more likely* to cause a global outbreak (or cause one of greater consequence) than those strains that evolved via natural forces. Note that although this study identified several types of risky, theoretical GoF experiments, many of these experiments have not been described in the literature. For example, no examples of researchers endeavoring to determine if seasonal influenza viruses could be made more transmissible were found. As another example, if a virus grows to a conveniently high titer naturally (e.g., 1E8 pfu/ml) then enhancing this level of growth may not be desirable or, indeed, biologically feasible. Moreover, many GoF studies are performed in highly attenuated strains, so that even though the risk of an outbreak increases if these strains were modified, risk is increasing from a very low level.

GoF Phenotype	Seasonal Influenza Viruses	1918 H1N1 Pandemic Influenza Virus	1957 H2N2 Pandemic Influenza Virus	Avian Influenza Viruses
Enhanced transmissibility	Increases probability of an outbreak and the consequences of an outbreak	Increases probability of an outbreak and the consequences of an outbreak		Increases probability of an outbreak and the consequences of an outbreak
Enhanced pathogenicity	Increases consequences		Increases consequences	
Adaptation to mammals	N/A	N/A	N/A	Decreases probability of an outbreak
Evasion of induced immunity	Increased consequences in high income countries only	Increased consequences in high income countries only	Increased consequences in high income countries only	
Evasion of natural/residual immunity	Increases probability of an outbreak and the consequences of an outbreak	Increases probability of an outbreak and the consequences of an outbreak		N/A
Antiviral resistance	Increased consequences in high income countries only	Increased consequences in high income countries only	Increased consequences in high income countries only	
Enhanced growth in culture/eggs		Increased chance of a LAI	Increased chance of a LAI	

Figure 6.1a. A figure showing increase in risk of research on modified influenza strains over wild type pathogens. The darker the shade of gray, the more a GoF phenotype increases risk of human illnesses and deaths. Marked in white are GoF phenotypes that are not relevant (N/A) to risk or reduce risk.

GoF Phenotype	MERS-CoV	SARS-CoV (R_0 1.6)	SARS-CoV (R_0 3.0)
Enhanced transmissibility	Increases probability of a global outbreak and consequences of a global outbreak	Increases probability of a global outbreak and consequences of a global outbreak	
Enhanced pathogenicity			
Adaptation to mammals	N/A	N/A	N/A
Evasion of induced immunity	N/A	N/A	N/A
Evasion of natural/residual immunity	N/A	N/A	N/A
Antiviral resistance	N/A	N/A	N/A
Enhanced growth in culture/eggs	Increased chance of a LAI	Increased chance of a LAI	Increased chance of a LAI

Figure 6.1b. A figure showing increase in risk of research on modified coronaviruses compared to wild type strains. The darker the shade of gray, the more a GoF phenotype increases risk of human illnesses and deaths. Marked in white are GoF phenotypes that are not relevant (N/A) to risk or reduce risk. This figure shows results assuming that the R_0 value of SARS-CoV is 1.6 (our baseline assumption) or 3.0.

In short, a strain of influenza virus that is as transmissible (or to which the population has as little minimal immunity) as newly emerged pandemic strains WHILE leading to a case fatality rate of more than 0.5% (the case fatality rate of the highly transmissible 1957 H2N2 pandemic strain) would pose more of a risk of a global pandemic than any wild type strain heretofore identified. No experiments that are likely to be conducted under the rubric of GoF research will drive risk more than this combination of traits or significantly increase the risk of a laboratory acquired infection. All other combinations of traits would lead to pathogens that have a lesser total risk than the wild type 1957 H2N2 strain. Increasing the transmissibility of the coronaviruses while significantly increasing the risk of work with those pathogens by several orders of magnitude still creates a pathogen that poses less of a risk of a global pandemic than the wild type 1957 H2N2 influenza strain.

In the brief section that follows, we provide the rationale behind these overall conclusions by showing how changes in each GoF phenotype affects each component of the risk assessment for each pathogen. Further supporting evidence is provided in this chapter in Section 6.4 and onward.

6.1.1 Seasonal Influenza Viruses

This risk assessment appropriately considers the fact that not all loss of containment events lead to a laboratory acquired infection, that not all laboratory acquired infections initiate a local outbreak (because of stochastic factors or the fact that infected workers may be given prophylaxis or be isolated), and that not all local outbreaks initiate a global pandemic. In fact, at each step, only a minority of events initiate the next step. Figure 6.2 shows the probability of each step in the chain of events that would eventually lead to a global pandemic from a loss of containment incident for wild type seasonal influenza, assuming that the previous step has occurred, assuming the work is conducted at BSL-2. From this figure, only 2% of laboratory acquired infections, which are rare in themselves (but not quantified by our method), start a local outbreak (that is, cause at least one secondary case) and only 20% of local outbreaks would seed a global pandemic. Moreover, in the case of seasonal influenza, the risk of a global pandemic is exacerbated by laboratory research only if that laboratory is working on a strain that has not circulated recently because residual immunity is likely to curtail its spread. If the strain is currently in circulation, the spread of the natural outbreak is likely to be driven by travelers, not by laboratory accidents.

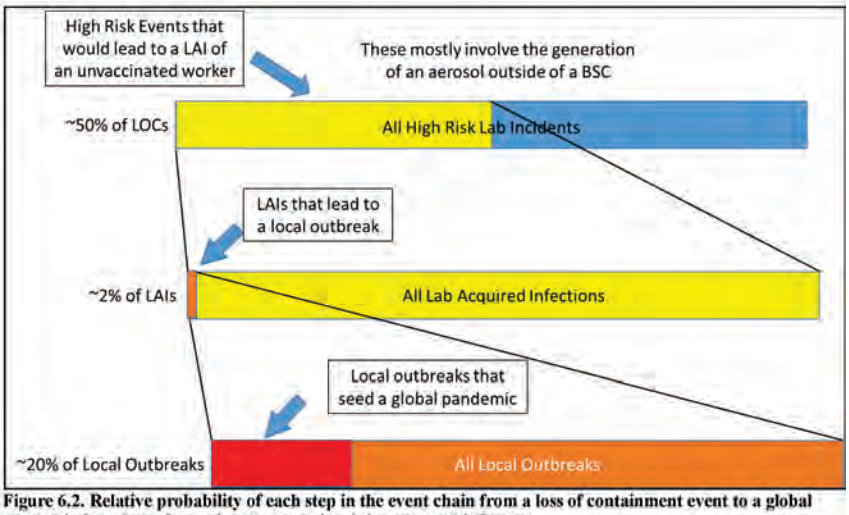

Figure 6.2. Relative probability of each step in the event chain from a loss of containment event to a global pandemic for a loss of containment event involving seasonal influenza.

To understand how GoF research could influence risk from research on seasonal influenza, it is useful to consider each step in the incident that leads from a loss of containment event to a global outbreak and to comprehend how the GoF trait would influence either probability or consequences at each step. Figure 6.3 divides risk by each step in the biosafety RA and shows how GoF research influences risk for seasonal influenza.

GoF Phenotype	Increase Probability of Lab Acquired Infection	Increase Probability of a Local Outbreak	Increase Probability an Outbreak Escapes Local Control	Increasing Global Consequences
Enhanced transmissibility	N/A	Less than 2x	2-3x	2x
Enhanced pathogenicity	N/A	N/A	Unknown—possible decrease in risk	10x or more
Adaptation to mammals	N/A	N/A	N/A	N/A
Evasion of induced immunity	Less than 2x	Less than 2x	N/A	4x in the high income countries only
Evasion of natural/residual immunity	Less than 2x	Less than 2x	2-3x	3-4x
Antiviral resistance	Less than 2x	Less than 2x	Unknown	5x in the high income countries only
Enhanced growth in culture/eggs	2x*	N/A	N/A	N/A

Figure 6.3. A figure showing increase in risk of GoF research on seasonal influenza over wild type seasonal influenza. The darker the shade of gray, the more a GoF phenotype increases risk of human illnesses and deaths. Marked in white are GoF phenotypes that are not relevant to risk (N/A), reduce risk or that could not be quantified. The star denotes a result that may not be statistically significant.

Because seasonal influenza viruses are associated with a low case fatality rate, increasing this rate could significantly increase the global death toll from an outbreak, increasing risk. Developing seasonal influenza strains that are more transmissible than wild type strains (approximately as transmissible as pandemic strains) or that overcome residual immunity increases the probability that an outbreak would escape local control and increases the consequences should a global outbreak be initiated. The creation of an antiviral resistant strain could increase the consequences of a global outbreak, but only in high income countries where caches of these antivirals could be handed out to a significant fraction of the infected population.

A strain of seasonal influenza that can overcome protective vaccination could also increase the consequences of an outbreak in high income countries, which has the resources to vaccinate their populations quickly. However, this phenotype is of concern only if it enables the virus to evade the protection afforded by means other than changing its antigenic properties, which is not a subject of current research in influenza.[336] (The vaccines made in response to an outbreak caused by a laboratory accident would be raised specifically against the strain causing the outbreak, so it would "match" the

[336] Clearly, this phenyotype increases risk given that enough vaccine could be produced in a short enough time to influence the outbreak caused by wild type strains.

novel antigenic properties of the strain.) The relatively small increase in risk due to vaccine resistance is not unexpected due to the modest efficacy of seasonal influenza vaccine at preventing infection.[337]

6.1.2 Pandemic Influenza Viruses

Figure 6.4 shows the relative probability of each step in the chain of events that would eventually lead to a global pandemic from a loss of containment incident for pandemic influenza at BSL-3. From this figure, less than 1% of high-risk loss of containment events, which are rare in themselves but not quantified here, involving wild type pandemic influenza would lead to a laboratory associated infection; only 5% of laboratory acquired infections start a local outbreak and only 20% of local outbreaks seed a global pandemic.

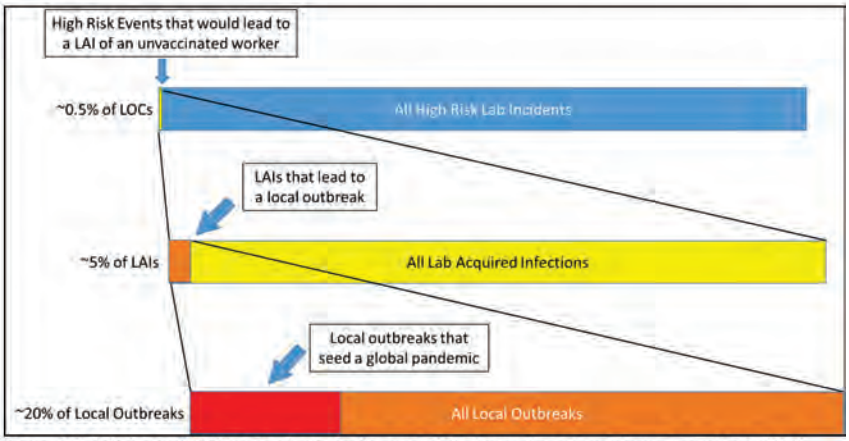

Figure 6.4. Relative probability of each step in the event chain from a loss of containment event to a global pandemic for a loss of containment event involving pandemic influenza.

Figure 6.5 divides risk by each step in the biosafety RA and shows how GoF research influences risk for pandemic influenza, assuming the strain manipulated is 1918 H1N1 influenza or 1957 H2N2 influenza. The risk analysis suggests that only two lines of GoF research could create a strain of pandemic influenza that poses more risk of a global outbreak than a wild type strain (in this case, the 1957 H2N2 pandemic strain). The first is the manipulation of a strain of 1918 H1N1 pandemic influenza that is modified to evade residual immunity (or otherwise increase transmissibility to the same degree). The second is the enhancement of pathogenicity (to that of 1918 H1N1 influenza) of a highly transmissible pandemic strain (e.g., 1957 H2N2 influenza). Imbuing 1957 H1N1 influenza with antiviral resistance can modestly increase the consequences of an outbreak, but only in countries with significant caches of antivirals. Enhancing viral growth in culture beyond that which is achievable in wild type strains (1E9 or 1E10/ml) increases the probability that a laboratory acquired infection would occur (by five- or 15-fold, respectively). However, it is doubtful if this phenotype is desirable or scientifically achievable because growth to 1E8 is sufficient for almost all purposes except the production of vaccines (using attenuated strains).

GoF Phenotype	Increase Probability of Lab Acquired Infection	Increase Probability of a Local Outbreak	Increase Probability an Outbreak Escapes Local Control	Increasing Global Consequences
Enhanced transmissibility	N/A	Less than 2x	Up to 3x increase	100X or more increase
Enhanced pathogenicity	N/A	N/A	Unknown—possible decrease in risk	Less than 2x
Adaptation to mammals	N/A	N/A	N/A	N/A
Evasion of induced immunity	Less than 2x	Less than 2x	N/A	Up to 4x increase in high income countries only
Evasion of natural/residual immunity	Less than 2x	Less than 2x	Up to 3x increase	100x or more increase
Antiviral resistance	Less than 2x	Less than 2x	Unknown	Up to 8x increase in high income countries only
Enhanced growth in culture/eggs	Up to 6x	N/A	N/A	N/A

Figure 6.5a. A figure showing increase in risk of GoF research on 1918 H1N1 pandemic influenza over wild type 1918 H1N1 pandemic influenza. The darker the shade of gray, the more a GoF phenotype increases risk of human illnesses and deaths. Marked in white are GoF phenotypes that are not relevant to risk (N/A), reduce risk or that could not be quantified.

GoF Phenotype	Increase Probability of Lab Acquired Infection	Increase Probability of a Local Outbreak	Increase Probability an Outbreak Escapes Local Control	Increasing Global Consequences
Enhanced transmissibility	N/A	Less than 2x	Less than 2x	Less than 2x
Enhanced pathogenicity	N/A	N/A	Unknown—possible decrease in risk	Up to 10x increase
Adaptation to mammals	N/A	N/A	N/A	N/A
Evasion of induced immunity	Less than 2x	Less than 2x	N/A	Less than 2x
Evasion of natural/residual immunity	Less than 2x	Less than 2x	Less than 2x	Less than 2x
Antiviral resistance	Less than 2x	Less than 2x	Unknown	2-3x increase in high income countries only
Enhanced growth in culture/eggs	Up to 6x	N/A	N/A	N/A

Figure 6.5b. A figure showing increase in risk of GoF research on 1957 H2N2 pandemic influenza over wild type 1957 H2N2 pandemic influenza. The darker the shade of gray, the more a GoF phenotype increases risk of human illnesses and deaths. Marked in white are GoF phenotypes that are not relevant to risk (N/A), reduce risk or that could not be quantified.

6.1.3 Avian Influenza Viruses

Wild type avian influenza is insufficiently transmissible amongst people to cause a global outbreak driven by the spread of the disease among humans. For this reason, no loss of containment event would lead to a global outbreak from a wild type strain.

Figure 6.6 divides risk by each step in the biosafety RA and shows how GoF research influences risk for avian influenza. Because wild type strains of avian influenza cannot spread globally between people, the creation of strains that are human transmissible would greatly increase the risk that such an outbreak could occur, which could cause millions of illnesses. The creation of a strain that is as transmissible as seasonal influenza would have a significant chance of sparking a global outbreak if a local outbreak were initiated. An increase in the pathogenicity in humans of the most pathogenic, wild type strains increases the consequences modestly only if one assumes that the case fatality rates of the most pathogenic strains of avian influenza are inflated by the underreporting of mild illness in people. Adapting avian strains to humans without increasing transmissibility (thereby lowering the median infectious dose in people) actually decreases risk because, while this trait increases the probability that a single laboratory worker would become infected, it decreases the risk that birds would become infected through an accidental release via the solid waste stream, which otherwise could lead to thousands of human infections and is the dominant loss of containment pathway. No other GoF trait increases the risk posed by avian influenza.

GoF Phenotype	Increase Probability of Lab Acquired Infection	Increase Probability of a Local Outbreak	Increase Probability an Outbreak Escapes Local Control	Increasing Global Consequences
Enhanced transmissibility	Less than 2x	Wild type strains cannot cause a local outbreak	Wild type strains cannot escape local control	Wild type strains cannot cause a global outbreak of human disease
Enhanced pathogenicity	N/A	N/A	N/A	Less than 2x
Adaptation to mammals	Decrease in risk	N/A	N/A	N/A
Evasion of induced immunity	Less than 2x	Less than 2x	N/A	Less than 2x
Evasion of natural/residual immunity	N/A	N/A	N/A	N/A
Antiviral resistance	Less than 2x	Less than 2x	N/A	Less than 2x
Enhanced growth in culture/eggs	Less than 2x	N/A	N/A	N/A

Figure 6.6. A figure showing increase in risk of GoF research on avian influenza over wild type avian influenza. The darker the shade of gray, the more a GoF phenotype increases risk of human illnesses and deaths. A numerical value cannot be provided for the greatest increases because the risk from wild type pathogens is vanishingly low for these outcomes. Marked in white are GoF phenotypes that are not relevant to risk (N/A) or reduce risk.

6.1.4 Coronaviruses

Figure 6.7 divides risk by each step in the biosafety RA and shows how GoF research influences risk for the coronaviruses. Recall that the RA uses the word "coronavirus" to mean the coronaviruses that cause SARS or MERS and not the coronaviruses that cause the common cold. Importantly, most estimates of the transmissibility of the coronaviruses consider these pathogens to be insufficiently transmissible and sufficiently susceptible to control measures such that a global pandemic has a very minimal chance of occurring. Even using the highest estimates of R_0 for SARS-CoV, derived from the location and time of an outbreak that caused the most secondary infections, results in less than a 10% chance of sparking a global pandemic should a local outbreak begin. For this reason, increasing the transmissibility of the coronaviruses could significantly increase the chance of a global pandemic due to a laboratory accident. That being said, even if these strains were modified to be as transmissible as pandemic influenza, the viruses' long generation time and lack of asymptomatic transmission, which results in susceptibility to control measures, the resulting outbreaks would still be contained a majority of the times they were initiated. Some researchers, using the strictest definition of R_0, have calculated the R_0 of SARS-CoV to be

3.0.[338,339] If SARS-CoV is indeed this transmissible, than the probability of escape or the consequences of a global outbreak are not increased significantly by further increases in transmissibility.

Increasing the pathogenicity of these strains could also increase risk somewhat through the increase in global deaths expected, considering most deaths from wild type strains are suffered by those with significant co-morbidities. Strains of the coronaviruses that have enhanced growth properties could increase risk of a laboratory acquired infection if samples with 1E9pfu/ml or 1E10pfu/ml were routinely manipulated in a laboratory (risk would increase by seven- or 25-fold, respectively). However, it is uncertain if this phenotype is desirable or even achievable because wild type coronaviruses grow to a sufficiently high titer for manipulations in the laboratory.

GoF Phenotype	Increase Probability of Lab Acquired Infection	Increase Probability of a Local Outbreak	Increase Probability an Outbreak Escapes Local Control	Increasing Global Consequences
Enhanced transmissibility	N/A	Less than 2x increase	Wild type strains are highly susceptible to local control	Several orders of magnitude
Enhanced pathogenicity	N/A	N/A		2-3x increase
Adaptation to mammals	N/A	N/A	N/A	N/A
Evasion of induced immunity	N/A	N/A	N/A	N/A
Evasion of natural/residual immunity	N/A	N/A	N/A	N/A
Antiviral resistance	N/A	N/A	N/A	N/A
Enhanced growth in culture/eggs	Up to a 10-fold increase in probability for a 1E10pfu/ml culture	N/A	N/A	N/A

Figure 6.7. A figure showing increase in risk of GoF research on coronaviruses over wild type coronaviruses. The darker the shade of gray, the more a GoF phenotype increases risk of human illnesses and deaths. A numerical value cannot be provided for the greatest increases because the risk from wild type pathogens is vanishingly low for these outcomes. Marked in white are GoF phenotypes that are not currently relevant to risk (N/A).

However, if a coronavirus were modified such that it caused a global pandemic (one in which sustained human-based transmission occurs in all global regions, which has never been observed), their relatively long incubation time and disease course (compared to influenza) would lead to a pandemic that unfolds over many years (Figure 6.8). While some outbreaks peak within two years, most require two to ten years to reach their peak. The fact that the outbreak evolves slowly gives public health authorities more time to adapt and expand their efforts to further contain the outbreak than the modeling conducted in this assessment suggests.

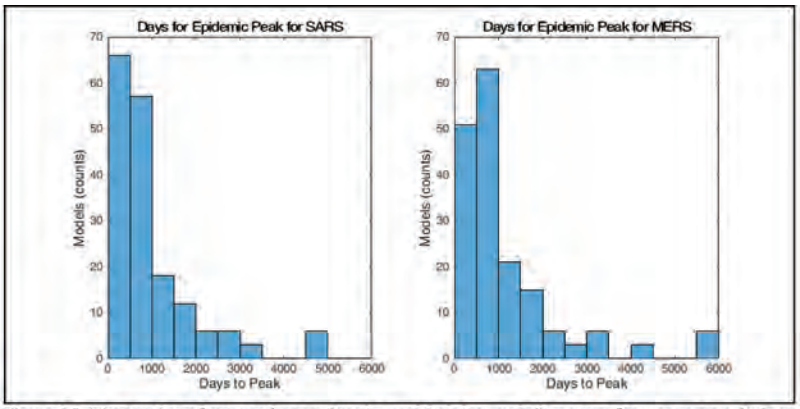

Figure 6.8. The number of coronavirus outbreaks modeled that peak (in terms of new cases per day) at any particular day after the global outbreak begins. To show the duration of truly global outbreaks, outbreaks that lead to less than one million infections are not shown.

6.2 Methodology

6.2.1 Purpose of This Task

The purpose of the quantitative biosafety RA is to provide information regarding the risk (in terms of consequences and probability) of a release of strains of pathogens with novel phenotypes that enhance their pandemic potential due to an accident or natural disaster. This assessment has three main components:

1. The estimate of the probability that an accident/natural disaster would occur and result in an infection of a human or other animal outside the laboratory,
2. The estimate of the probability that an outbreak that occurs would escape beyond local control and seed a global outbreak, and
3. The estimate of the extent of an outbreak that would result from an infection outside the laboratory.

Critically, because GoF research occurs in a world in which research on dangerous, wild type pathogens is ongoing, the risk assessment is comparative. That is, we seek to determine how much risk *increases* if GoF research proceeds.

6.2.2 Input from Modeling Subject Matter Experts

To guide our modeling effort, we interviewed the following infectious disease modeling subject matter experts (SMEs): Dr. Jason Asher, Dr. Steven Riley, Dr. Martin Meltzer and Dr. Carrie Manore.[340,341,342,343] Their input is reflected in the modeling methodology described in this section. All of the interviewed experts unanimously agreed that the use of multiple models, covering event initiation, initial local spread, and potential global outbreak, respectively, is reasonable and sound. Additionally, all experts confirmed that the choices of a stochastic approach for the initiation phase of an outbreak followed by a homogenous mixing, deterministic approach for modeling the global spread phase were appropriate. Mr. Asher spoke about the BARDA Interactive Flu Model, an SEIR-type model, and confirmed that it contained the necessary features for the biosafety risk analysis; this model became the basis for global outbreak simulations.

When asked about appropriate stochastic models for the initiation phase of the outbreak, Dr. Riley suggested that, in lieu of a computationally-intensive agent based model, a branching process model may be more appropriate. He believed that such an approach would capture the key features of such an outbreak, while leaving out dimensions that were not critical in determining whether an outbreak would grow beyond local control, such as where infected individuals lived. He also remarked that branching process models would capture a critical facet of laboratory acquired infections: that most of them do not lead to outbreaks of significant size. Moreover, an agent-based model would require the parameterization of features of the environment of the outbreak that would be unknowable. Dr. Riley emphasized the criticality of the shape of the offspring distribution in such a model and suggested we speak with Dr. James Lloyd-Smith, with whom Gryphon collaborated and consulted on the development of the branching process model used in the final risk analysis.[344] All other interviewees to whom a branching process model was mentioned either raised no objections or confirmed the appropriateness of the approach.

In searches of the literature, little data and few models covering zoonotic infections of influenza were found. Dr. Manore agreed that relatively little data existed, particularly for interspecies contact rates, and that few people were considering models that incorporated humans, domestic animals, and wildlife in a single model. She remarked that their approach to overcoming this lack of data in their influenza models was to parameterize based on a retrospective analysis of prior outbreaks to ensure that the predictions of the model were reasonable. This approach is clearly not suitable for a prospective analysis such as ours.

6.2.3 Interplay of the Components of the Biosafety Risk Assessment

The biosafety RA has several components that will be married together to understand how risk of a laboratory accident changes if GoF experiments proceed. These components and their interplay are shown in Figure 6.9.

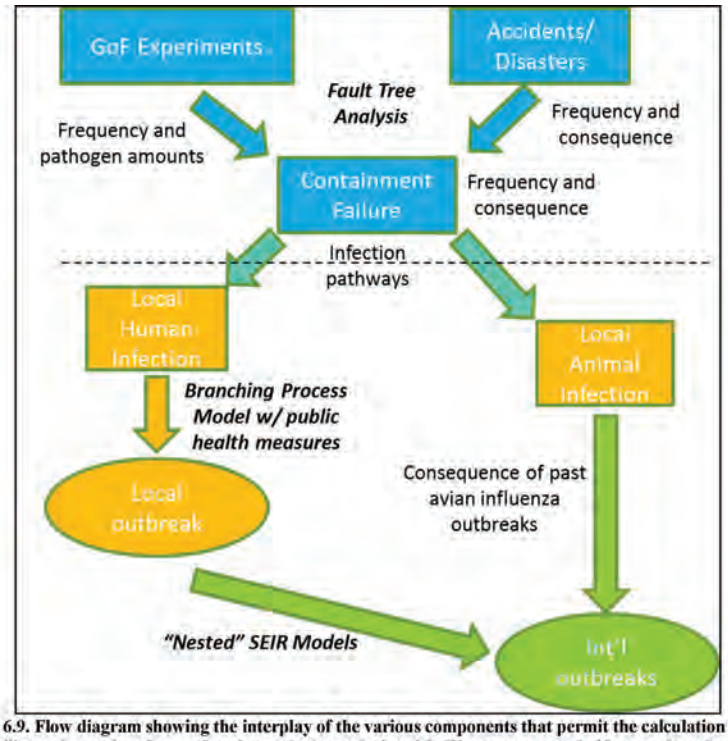

Figure 6.9. Flow diagram showing the interplay of the various components that permit the calculation of the probability and severity of an outbreak to calculate relative risk. The components in blue speak to the probability that an infection outside the laboratory occurs. The components in orange speak to the probability that an outbreak will escape local control and cause a global pandemic. The components in green speak to the consequences of a global outbreak. Quantitative modeling approaches are shown in bold italics. All components are considered together to understand probability and consequence using a Probabilistic Risk Assessment framework.

To inform the RA, we interviewed 77 Subject Matter Experts as shown in Figure 6.10. These stakeholders provided data on the frequency of GoF experiments and the experimental conditions, containment features, health surveillance procedures, isolation procedures, and public health response measures that occur in their laboratories.

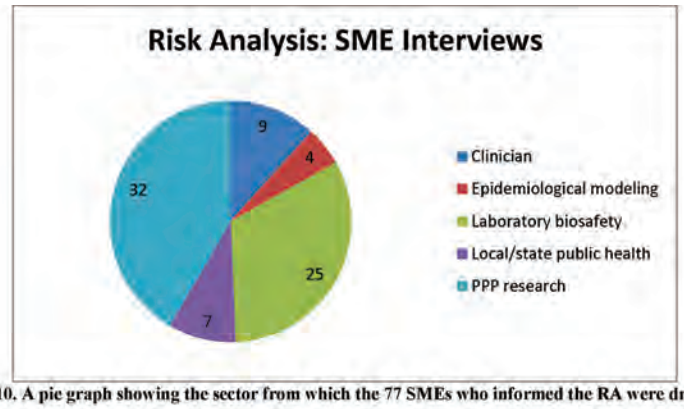

Figure 6.10. A pie graph showing the sector from which the 77 SMEs who informed the RA were drawn.

6.2.4 Taking a Parametric Approach to the Analysis

Perhaps the most challenging aspect of this effort is to assess the risk of experiments that have yet to occur in locations that haven't been identified performed under unknown biosafety conditions. If there were a finite number of phenotypic changes to the pathogens of interest, a finite number of experimental procedures used, a small number of possible locations for the research or a finite number of conditions under which the research could occur, we could simply test each one. However, this approach is not feasible and would not provide the NSABB with the information it needs to make recommendations and for the USG to formulate policy.

Worse still, drawing a "bright-line" boundary between research that qualifies as GoF and research that does not is likely to be difficult. Even for experiments of the same type, the specific strains selected, the quantities used, and the intended outcomes matter greatly; the context of the research is key. As a result, without a method that allows an examination of the details of each experiment and the pathogens therein, accurately assessing the relative risks of each would be difficult, if not impossible.

For this reason, the power of the modeling approach was exploited to explore the entire space describing each quality of GoF and wild type pathogens used, the experiments undertaken, the laboratories, and the containment measures where the experiments occur. This type of approach is called "parametric analysis" because each quality, or parameter, is allowed to vary across a range of possible values. This approach enabled not only the accurate assessment of the risk of future experiments, but also can be used to support the development of generalizable guidelines after important drivers of risk are identified.

This approach was applied to the pathogens themselves, for which the following parameters were allowed to vary, including:

- Pathogenicity in humans (including case fatality rate and infectious dose),
- Transmissibility in humans,
- Evasion of diagnostics and countermeasures, including vaccines and antivirals,
- Evasion of immunity, either natural or induced, and
- Growth in culture or eggs

The approach was applied to the experimental conditions, for which the following parameters were allowed to vary, including:

- The number and type of infected animals,
- The frequency animals are physically handled,
- The concentration and volumes of stocks and infected tissue culture samples, and

Although we considered pathogens with a range of characteristics, any of these pathogens were considered to have arisen from an already established strain of virus in terms of the experiments conducted and epidemiology. Moreover, we specifically parameterized and modeled wild type influenza viruses (seasonal, pandemic and avian), MERS Co-V, SARS Co-V (to establish the baseline for relative risk), and the strains that have arisen from GoF experiments already (to identify any change in risk).

This approach was applied to the laboratories that may perform the work, for which the following parameters were allowed to vary, including (a full list is available in the Supplemental Information):

- The existence and effectiveness of various containment features,
- The existence and effectiveness of various pieces of personal protective equipment (PPE),
- The existence and effectiveness of decontamination procedures,
- The existence and effectiveness of monitoring systems for the health of the workforce, and
- The population density of humans outside the laboratory,

To understand risk of GoF work when performed under less-than-ideal circumstances, as may be the case in other parts of the world, we can assess how the removal of any particular containment feature, decontamination procedure, or health monitoring procedure would affect the probability of a release.

6.2.4.1 Bounding the Parametric Approach in Science

The parametric analysis described above is also underpinned by scientific data. That is, a parameter could be allowed to vary between any arbitrarily large or small value but is grounded by information related to the attributes of known pathogens. For example, the contagiousness (which could be measured in the number of naive people an infected person can infect) could be allowed to vary from zero to the entire population of the earth. However, given data on real viruses, we know that this parameter value would rarely exceed ten and only when describing the most contagious viruses known. Moreover, the possibility that a modified avian influenza virus becomes *more* contagious than any influenza virus that has ever been observed stretches reason. Similarly, even though the parametric analysis will allow the systematic removal of containment features, it is highly unlikely that GoF experiments would proceed without any containment whatsoever. As another example, an extremely risky strain of influenza virus may be one that could be simultaneously transmissible in poultry and humans, however such a strain may not be possible due to the nature of the changes in viral receptors that lead to changes in species tropism.

Our parametric analysis allowed us to evaluate how risk changes as the GoF research features change. The possibility that risk increases significantly only when a parameter reaches an unrealistic value builds confidence in the fact that our model is capturing all possible facets of risk. At the same time, this counterfactual analysis provides some information as to which manipulations or settings are unlikely to pose a significant increase in risk over work with unmodified pathogens.

Although the intent was to develop an RBA approach that is flexible enough to encompass all possibly risky manipulations of any pathogen, many aspects of a pathogen's lifecycle (and its epidemiology) are unique, and therefore models that faithfully replicate the risk of outbreak initiation and spread must use

real examples. Moreover, the experimental conditions used in GoF experiments (volumes, titers, cell lines, animal models, etc.) are also unique to the pathogens used in the experiments. Due to the focus of GoF concerns on influenza and coronaviruses, we used these viruses as the basis of our work in this study.

6.2.5 Probability of an Infection Outside of Containment

6.2.5.1 Choosing the Incidents to Model in Detail

To estimate the probability that an accident or natural disaster (together called incidents) leads to an infection outside the laboratory, we treated each separately. There are several types of incidents that could cause a loss of containment and a subsequent outbreak outside a containment laboratory. To identify the incidents to model, we leveraged previous laboratory risk studies and reports on past incidents to understand which incidents most drive risk of outbreaks caused by incidents at containment laboratories. Minor accidents, which do not drive risk because they were found to be unlikely to cause an infection or to have minimal consequences should they occur, need not be considered in detail. Recall that because risk is the product of the consequence and frequency of an adverse event, the riskiest accidents to examine include a variety of types: 1) those that are frequent and low-consequence, 2) those that are rare and high-consequence, and 3) those that are not uncommon and of moderate consequence. After the identification of the incidents that drive risk, the remainder of the biosafety RA analysis focuses on the evidence basis and modeling of only these most risky accidents. We further winnowed out incidents that were found to be minimally risky in the context of GoF research.

We collected past laboratory RAs and Environmental Impact Assessments (listed in Appendix III). For all studies that quantitatively assess risk in terms of probability and consequence, we identified the highest risk incidents and gathered all data related to those incidents. For studies that simply detail scenarios that are deemed to be "maximum reasonably foreseeable events" or a "plausible, worst case" scenario, we determined if quantitative studies examined similar incidents and where they fall on the risk ranking. As these types of scenarios are typically chosen because they have maximal consequences, without a consideration of probability of the event occurring, it is possible that these so-called "maximum reasonably foreseeable events" or "plausible, worst-case" scenarios are so vanishingly unlikely (i.e., occurring less than once in a billion years) that they do not affect risk much, even though they are consequential when they occur. If these scenarios were found to be relatively low risk, they were excluded from further analysis. If they were assessed in other quantitative risk assessments or there was no other reason to exclude them, they were included in our Fault Tree Analysis. This process explicitly captures the low-probability (but plausible), high-consequence events.

To supplement our list of high-risk accidents from previous assessments, we examined accident reports and case studies (sources are listed in Appendix III). Importantly, historical incidents are supported by a minimal amount of quantitative information (mostly related to consequence) that prohibits an estimate of risk. Just because an accident occurred once, we cannot calculate the probability that it would happen again. For this reason, we compared the list of historical accidents to the list of incidents to model from past RAs. Also, we found that many incident reports are included as high-risk incidents in past RAs (for instance, "spill") and other incidents are components of an overall sequence of failures that leads to a release in a past RA. For example, "PPE failure", which is mentioned in accident reports, is a possible failure node in all incidents that involve the generation aerosols or splashes on personnel. We included these types of events in several fault trees to assess the influence of the failure of these systems on risk of another incident (such as a spill). From these riskiest accidents, we removed those accidents that do not apply to the pathogens we are considering. For example, the National Bio- and Agro-defense Facility Site Specific Risk Assessment conducted for the Department of Homeland Security in 2012 identifies several

risky accidents arising from the fact that their pathogens are studied in large animals (like cattle), which can physically break containment features.

The list from previous studies and reports consists of the riskiest incidents that cannot be discounted from previous studies, the most common accidents that could lead to an infection outside a laboratory, any accident that did lead to an infection outside the laboratory (that cannot be discounted), and all "maximum reasonably foreseeable events" that could not be shown to be lower in risk than incidents included.

Even though the highest risk accidents are unlikely to change much in their frequency regardless of the nature of the pathogen, the probability that an infection outside the laboratory could occur may be significantly different. That is, although the chance that a centrifuge rotor breaks is the same if the sample inside contains viruses or bacteria, the chance that an infection may occur outside the laboratory if a worker caries infected material out on his shoe may be different if the contaminant were Foot and Mouth Disease virus versus influenza virus. For this reason, we determined if the pathogens of particular interest in GoF studies, specifically influenza viruses, MERS-CoV, and SARS-CoV, pose unique risk pathways that must be investigated further due to dissimilarities of their biology, pathogenesis, host range, or life cycle compared to the pathogens considered in past RAs. From this qualitative analysis, we identified further accidents to consider to capture the unique risks that these pathogens may pose. Specifically, animal bites were a "low risk" incident in past RAs, but ferrets, an animal model of choice in influenza studies, are particularly prone to biting (which, although the risk of infection from the bite is unlikely for respiratory pathogens, could deposit pathogen directly on the skin, increasing the risk of self-inoculation into the eye or nose). An "incident" modeling the fact that infected animals are constantly exhaling pathogen (called "animal respiration") was also specifically included because, unlike in other laboratories, infected animals pose a direct hazard to unprotected workers (should containment fail). All highest risk, relevant incidents from past studies and case reports were combined with these additional selected incidents to define the list of high-risk incidents that we were investigated in detail.

6.2.5.2 Predicting the Amounts and Pathways of Pathogen Releases for Accidents

To assess the probability that an accident would occur resulting in a loss of containment, we used Fault Tree Analysis (FTA), an accident modeling approach in which each possible system component that could fail in a complex pathway to an accident is explicitly parameterized with probability and consequences of failure. We implemented this FTA using Monte Carlo simulations, an approach that randomly samples values from all possible parameter values to explore the effect of uncertainty on our analysis. This approach was used to determine the probability that an accident occurs while an experiment with a dangerous pathogen is taking place (or in the handling or shipment of a pathogen) and the amount of material that escapes containment. Should an accident occur, there will be consequences in terms of the material dispersion. The dispersed material will then be subject to elimination or retention due to decontamination procedures and containment systems. The fact that many accidents may not be apparent when they occur is important to consider because additional measures are usually implemented when overt accidents occur. The accident could generate an infectious aerosol, fomites, or living carriers (laboratory animals or workers). We also considered the possibility that an accident generates many types of sources (a centrifuge spill could create an aerosol, fomites, and infected workers).

For accidents, the frequency of experiments and the concentration of the stocks and samples manipulated were estimated to describe the "opportunity space" for accidents to befall. These data were gathered in site visits and interviews with PPP researchers. Once an accident occurs, the agent may be released but will still be inside of containment. The effectiveness of containment measures determines how much material leaves containment depending on the nature of the accident. Containment measures reduce the concentration of a biological release, but may not be in place/functioning where the accident occurs due

to human error (e.g., mislabeling/mishandling of a sample) or equipment failure. Data on the failure of mechanical systems and of human error rates were derived from the scientific/engineering literature. Data supporting the Fault Tree Analysis are provided in the Supplemental Information along with full descriptions of the Fault Trees. Given the role of humans in historical laboratory accidents, our FTA includes a robust consideration of human reliability in the execution of appropriate decontamination and safety procedures.

Any material that escapes containment and decontamination described a source term that is used to model the initiation of an infection outside the laboratory. Aerosols were described by their quantity in a respirable range. Fomites were described by their material, location, and quantity. Infected people and animals were described by their type and quantity. Insofar as an accident causes consequences inside the laboratory to the workers, these casualties were tallied as consequences.

6.2.5.3 Source Terms for Natural Disasters

For natural disasters, we estimated, at any given time, how much pathogenic material is in the laboratory that could be released. This pathogenic material could be in the form of stocks in storage, samples being manipulated, or infected animals. The disaster itself may lead to several events inside the laboratory (the spill of materials or the release of animals) and the disruption of containment systems (over pressuring of HEPA systems or breach/failure of a building envelope). Several infection pathways could simultaneously lead to outside infection after a natural disaster (an earthquake could lead to the generation of an agent aerosol and the escape of infected animals). FTA was used to determine the probability that a natural disaster occurred and affected pathogen stocks, infected animals, or experiments in progress. As described above, we examined only those natural disasters that are deemed to be high risk. The dispersed material will then be subject to elimination or retention due to decontamination procedures and containment systems, although these may be compromised due to the disaster. Natural disasters cannot be covert, and so we assume that special public health measures (such as social distancing or restrictions on movement) would be implemented if a natural disaster is known to strike a containment laboratory.

Any material that escapes containment and decontamination helps describe a source term that was modeled for its ability to cause an infection outside of a laboratory. The source terms were described similarly to those arising from accidents.

6.2.5.4 Modeling Initiation of an Infection Outside a Laboratory

Once infected material leaves the laboratory, it may cause infections in nearby human or animal populations. The probability of the infection occurring depends on the nature of the source term, which can be aerosols, fomites, or infected animals/researchers. Each type of source term was modeled using a separate methodology.

Indoor and outdoor source terms were modeled separately. Indoor source terms were modeled as if the worker causing the accident inhaled all of the aerosol to understand a maximum level of risk. We chose this approach because a worker who creates an aerosol is exposed to a relatively high concentration of the contaminant until it disperses within the room. Workers who did not create the aerosol are exposed by dwelling in a completely well-mixed space that is slowly exhausted to the outside. Any material escaping the building was modeled using the Hazard Prediction and Analysis Capability (HPAC), a model developed by the Defense Threat Reduction Agency which is able to predict the transport and downwind infections over large areas given real population densities. We chose two laboratory locations to understand the range of risk from aerosols, New York City—the urban area with the greatest population density in the US— and a small town. Real weather data for those locations was used. One hundred

releases were modeled ranging over a variety of times of year and times during the work day. HPAC was used to calculate the dose that people downwind received. Dose/response curves were used to determine how much of the population inhaling the pathogen becomes infected. Given data on the populations of susceptible animals (specifically ducks) and their minute tidal volume (the amount of air they inhale per minute), we calculated animal infections over the same area.

For infected animals that leave the laboratory due to a natural disaster, we presumed that an outbreak is initiated by the animal encountering a human before it expires (for human-transmissible pathogens) or by encountering a susceptible bird (for bird-transmissible pathogens). For infected animals that leave the laboratory because they are carried out intentionally in a malicious act (relevant to the biosecurity RA below), we presumed that the malicious actors are themselves infected (for human-transmissible pathogens) or that the infected animal encounters a susceptible bird (for bird-transmissible pathogens). For the animal escape incident in the biosafety RA, our FTA models predict the animal leaving the laboratory is vanishingly unlikely (by bolting, unnoticed through several self-closing doors) and instead drives risk by escaping containment features within the lab and infecting workers.

For infected workers, we created a separate FTA that accounts for their behavior, the possible violation of health monitoring procedures and isolation guidance and their contacts with susceptible individuals throughout their disease course. Some protocols are initiated only if the exposure event was overt and considered high risk (an observed spill for example). Other protocols, such as the reporting of influenza-like illness and isolation should such symptoms appear, occur regardless of the type of accident that caused the illness. Workers may violate protocols (via ignorance or arrogance), and these workers enter into the models of local infection, as described below. Also, a worker could initiate a local outbreak if they develop no clinical symptoms or develop transmissible illness prior to the onset of symptoms.

For fomites, we developed a stochastic, Markov chain model to predict the likelihood of an outbreak initiating after a laboratory worker leaves containment with virus on his or her person. The model tracks the contamination through the paths it must take to result in infection of the initial laboratorian, of one or more household or community members, or of avian species on a farm (or any combination of the three). All infections are the result of internalization of the virus from a contaminated surface or body part; that is, this is a model of contamination transference and subsequent infection, not a model of contagious transmission. The transference model utilizes Monte Carlo simulations to estimate the likelihoods of a number of possible actions that would lead to internalization, spread, or removal of the virus. Human infection occurs when viral contamination on a person's hand enters their mucosal membranes of the eye, nose, or mouth, and the probability of infection is dose-dependent based on the calculated amount of virus present at the time of inoculation. For an animal infection to occur, the primary laboratorian must encounter a susceptible species, at which point it is assumed that all of the virus is inoculated into the animal. For animal contact to occur, the worker may need to violate quarantine protocol, which occurs at a specific probability, after which visits to an animal facility occur at a predetermined rate, as with the events above.

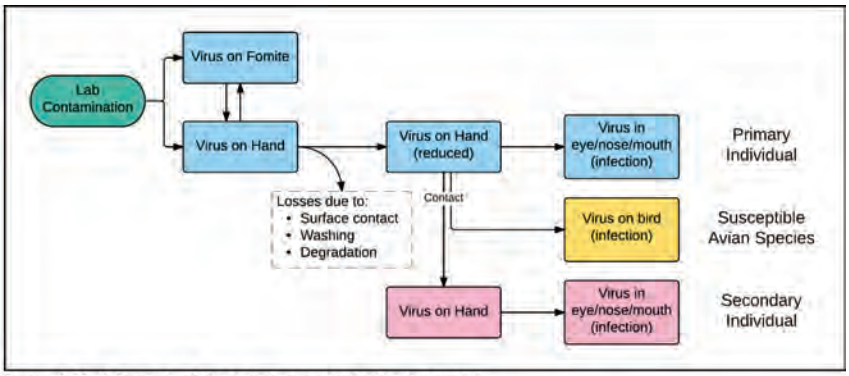

Figure 6.11. Schematic of the transference and infection model.

For the data supporting the parameter values used in the models that support the estimate of source terms causing infections outside the laboratory, please see the Supporting Information.

This analysis predicts the probability that an outbreak would be initiated by human or avian infections outside the laboratory for each of the possible incidents modeled. These incidents can vary by the species infected (ducks or people), the type of person infected (laboratory worker or a member of the public) and the number of people infected.

6.2.6 Predicting the Probability That an Outbreak Escapes Local Control

Once a human-transmissible disease leaves the laboratory and infects at least one person outside of containment, an outbreak is initiated (recall that health monitoring and isolation/quarantine measures enacted for exposed laboratory workers are already considered before the outbreak occurs, as described above). Depending on the release, an outbreak can start with one or more initial cases. For example, a large aerosol release from a catastrophic incident (like an earthquake) could infect many dozens of people. We considered outbreaks that initiate with the infection of a laboratory worker differently than outbreaks that begin with a member of the public because we presume that laboratory workers (and their families) would be more likely to report to public health authorities if they developed unusual symptoms of infectious disease and would be more likely to self-isolate.

An outbreak that starts with a handful of people is governed by stochastic forces that could, by chance, cause the outbreak to extinguish. Similarly, an outbreak that is recognized early and subjected to vigorous control measures may extinguish.

To model the local outbreak, we used a branching process model, developed by, and in consultation with, Dr. James Lloyd-Smith (UCLA), a recognized world expert in stochastic epidemic modeling.[345] Branching process models are stochastic, where each case creates a number of new cases based on a probability distribution. In the model used in this report, the distribution is a negative binomial distribution with parameters R_0 (the average number of new cases each case generates) and k (which reflects the variation in infectiousness between individuals, where low values of k imply high variation

[345] J. O. Lloyd-Smith, S. J. Schreiber, P. E. Kopp & W. M. Getz. Superspreading and the effect of individual variation on disease emergence. *Nature* 438: 355-359 (2005)

and high values of k imply low variation). Low k is appropriate for MERS/SARS because most people create no secondary cases, whereas some create a very large number. Higher k is appropriate for flu because many people infect one or two others, some zero, some a large number. The range of values used for R_0 and k for wild type strains of influenza and coronaviruses is provided in the Supplemental Information. Branching process models capture one crucial feature of new outbreaks: that many new outbreaks extinguish at a small number of cases.

The branching process model we adapted considers various control measures and can account for partial immunity in the community (important for outbreaks of recently circulating influenza strains). Social distancing and isolation/quarantine are parameterized. Because our analysis is not to evaluate control measures but to compare the risk of various outbreaks, we explore a variety of plausible values for the parameters describing these measures. The parameter values that describe control measures are described in the Supplemental Information. Notably, our model tracks laboratory workers and community members separately so that we subjected each to different control measures.

In our analysis, an outbreak was considered to be out of control if either of the following conditions were met:

- The model calculated that, given the number of cases in the current generation, that the outbreak had less than a 5% chance of extinguishing at any point in the future, or
- That any generation included more than 1,000 infected individuals (which probably outstrips the ability of a locality to control), or
- The model includes 200 generations of infected individuals without extinguishing or reaching any other termination condition (suggestive of never getting under control).

In this Risk Assessment, 2.6 billion simulations were performed in our BPM to provide statistically sound data to explore the parameter set for wild type and GoF pathogens and a variety of outbreak control parameters.

Once an outbreak was considered out of control, it was considered to seed outbreaks globally. The illnesses and deaths due to an outbreak that extinguishes either due to stochastic forces or due to control measures were tallied as part of the consequences of the local outbreak.

6.2.7 Modeling the Global Consequences of a Human-Transmissible Outbreak

Once an outbreak was found to grow out of local control using the branching process model, we modeled the global consequences of a pandemic using the HHS-BARDA Interactive Influenza Model (IIM), which is used by the Centers for Disease Control and Prevention and HHS-BARDA to evaluate the effectiveness of medical countermeasure strategies to control influenza outbreaks.[346] IIM is a "Susceptible, Exposed, Infectious, Recovered" (SEIR)-based model, which is a compartmental epidemiological model which tracks the progression through various stages of a disease course of individuals in an outbreak. IIM considers the differences in vaccination and clinical visit rates of different age groups (children, adults, and the elderly), contact rates between these groups, and control measures, like mass vaccination, social distancing and antiviral treatment.

[346] For example, see Biggerstaff, M et al "Estimating the potential effects of a vaccine program against an emerging influenza pandemic--United States." Clin Inf Dis S1: S20-9 (2015).

IIM was developed using contract rates and demographic data for the US. To globalize the model, we collected demographic data for 12 regions of the world, divided by geography and income (with the rationale that high-income countries have distinct demographics and public health resources than other countries). We characterized each region by population, class size (used to scale school-based contact rates), household size (used to scale household contact rates), and age stratification (used to scale relative numbers of children and the elderly). The methodology for scaling contact rates is described in Appendix III Section 14.3.1 and the demographic data supporting the regionalization of the globe is provided in the Supplemental Information. Although this method captures some demographic differences between regions of the world, it does not capture cultural practices and socioeconomic factors (like underlying poor health) that could affect the outbreak. Also, public health measures, like social distancing, are assumed to be equally effective in all parts of the world (however, vaccine doses and antivirals are more limited).

If an outbreak escaped local control, we assumed that it would continue to seed infections in the US and a US-wide outbreak will continue to seed outbreaks abroad. For this reason, travel rates were unnecessary to obtain as eventually the disease would spread. Each region was seeded with 100 initial cases. Parameter values used in the IIM model are provided in the Supplemental Information.

To support the analysis in this Risk Assessment and adequately explore the parameter space, the IIM ran approximately 750,000 simulations.

6.2.8 Simplified Modeling of Bird-Transmissible Pathogens

One hypothetical consequence of a laboratory release of research with a strain of influenza that is transmissible only amongst avian species is that the strain could establish itself in wild bird populations (by infection via an aerosol, contaminated worker, or contaminated waste leaving the laboratory), causing sporadic human disease over a dispersed geographic area, similar to the natural H5N1 strain today. For this eventuality to occur following loss-of-containment and subsequent release, a series of events must occur: the virus must reach an environment where infection of a wild bird can occur; it must infect a wild bird; the virus must spread and migrate with a population of birds; these infected wild birds must then spread the virus to a domestic bird population; this virus must then spread from the domestic birds to humans; and finally, the virus need be capable of causing disease in a human host. Note that a virus that spreads between humans is presumed to spread between humans efficiently and any incidental transmission from birds will not significantly affect the kinetics of the outbreak; hence, this section does not consider human transmissible viruses. This presumption is supported by the opinion of several of the interviewed experts, who believed that a Gain of Function influenza virus, including the H5N1 strains adapted to transmit between ferrets by the airborne route, could be adapted to spread efficiently among humans or among birds, but not between them due to differences in viral receptors in these animals. This belief agrees with the historical evidence, as we have yet to identify either a natural human influenza that spreads easily among birds or a natural avian adapted virus with sustained mammalian transmissibility.

6.2.8.1 Unpredictability of the Consequences of Novel Avian-Influenza Strains

Determining the probability and consequences of each of the events necessary for an avian virus to infect humans is very difficult primarily due to missing data. For example, one reference reviewed 4,763 literature sources of human to animal transmission of any disease, and found no documented examples of direct human to animal transmission of influenza.[347] Similarly, despite detection of influenza in natural water sources and measurements of the persistence of influenza in water suggesting that "cloacal

[347] Messenger AM *et al* (2014) Reverse zoonotic disease transmission (zooanthroponosis): a systematic review of seldom-documented human biological threats to animals. *PloS one* 9: e89055

drinking" by waterfowl of contaminated water may be a source of infection, no identified source listed an ID_{50} for such a process.[348,349,350] However, of the sources of uncertainty, estimating the consequences to humans of a flu circulating in wild birds remains the largest due to uncertainties in the biology of the virus and the role of human-avian interaction in its epidemiology.

Despite intense research efforts spanning decades, predicting the transmissibility and pathogenicity of a new or novel avian strain in humans or other mammalian hosts remains challenging. Part of this difficulty stems from the diverse range of symptoms and effects seemingly similar strains cause, combined with the apparent uncorrelated symptom severity between birds and mammals. Shown in the Supplemental Information are data for eleven recent avian influenza outbreaks, eight of which have caused human cases. Comparing the outbreaks reveals the unpredictability of human effects. For example, despite the virus that caused the 2015 H5N2 outbreak containing a hemagglutinin (HA) in the same clade as one known to cause fatal human H5N1 infections, the H5N2 outbreak has of yet caused no known human cases of infection.[351,352] This difference could be behavioral (due to enhanced biosafety practices in the poultry industry in the USA) or may be due to differences in biology of the strains. The H7N7 outbreak of 2003 caused only one human fatality, and most symptoms were restricted to conjunctivitis even though the strain appeared highly infectious to humans, with 250/500 of potentially exposed humans tested showing evidence of seroconversion.[353] In comparison, the ongoing H7N9 outbreak causes minor to no signs in either wild birds or poultry, but causes severe respiratory disease in humans in the relatively few human cases it has caused.[354]

The distribution of an outbreak is as unpredictable as its transmissibility and pathogenicity. The majority of poultry outbreaks of influenza remain constrained to one or a few flocks, with a few spreading much further. The current outbreak of H5N1 began in December 2003 with the first reported human cases in Vietnam and spread rapidly.[355] By April 2004 it had spread to Thailand, Korea, Japan, Indonesia and Hong Kong and by November 2004 to mainland China. By February 2006 it had become intercontinental, spreading to Europe as well as Africa where it remains endemic to Egypt. The timing and location of spread appeared to correlate with bird migratory patterns, hinting at wild bird-mediated spread.[356,357] In contrast, H7N9 began in the same global region, and appeared to initially spread more quickly, yet despite beginning in the same region and presumably being subject to the same cultural and geographic factors, it has only spread through a geographically contiguous area and not spread internationally, confounding determination of whether the spread is primarily wild bird or human mediated.[358] Meanwhile, the North

American H5N2 outbreak began in the Pacific Northwest and quickly jumped two migratory flyways to the Midwest; the mechanism for this rapid eastward spread has not yet been identified.

The lack of a solid scientific evidence basis for predictive epidemiology in avian influenza viruses implies that any serious quantitative analysis would be unfounded. For this reason, we took a simplistic approach to modeling outbreaks of influenza viruses that spread between birds only.

6.2.8.2 Spread of Escaped Laboratory Virus to Wild or Domestic Birds

First, avian-influenza strains are modeled in the Fault Tree Analysis like any other strains. We have enough data to predict the chance of infection of a human or a bird when exposed to a source of pathogen. We can therefore quantitatively predict if humans or animals are infected within the laboratory (due to a variety of incidents) or outside the laboratory (due to aerosols or transfer of contamination from a worker to poultry). Should a bird be infected outside the laboratory or an infected bird escape from the laboratory (in the earthquake and biosecurity scenarios), we presume that an avian influenza outbreak occurs and has consequences similar to the recent outbreaks. That is, we presume that between 0 and 1,000 human infections occur and that the case fatality rate is between 0 and 50%. Given the lack of data, our model presumes an equal probability of any result in this range. Because we are not estimating economic consequences or risks to animal health, this approach is sufficient to characterize the risk of this agent to humans given the paucity of data available.

Recall that if the pathogen is transmissible between people (regardless of if the strain is a natural one or if it is a modified avian-influenza strain), we modeled the outbreak assuming that all human health risk is dominated by human-to-human contact.

6.2.9 Estimating Risk of Experiments Involving GoF Pathogens

Each modeling component is used to predict a single aspect of risk:

1. The Fault Tree Analysis is used to determine how pathogen characteristics, containment features, experimental manipulations and the laboratory environment contributes the *probability* of escape, and the number of cases that would initiate an outbreak (a component of consequence),

2. The branching process model estimates the *probability* that a local outbreak would grow and seed a global pandemic. If the outbreak extinguishes due to stochastic factors or due to an effective public health response, the *consequences* from the local outbreak are tallied, and

3. The HHS-BARDA Interactive Influenza Model is used to predict the global *consequences* of a pandemic.

By linking the outputs of the modeling component, we can state how much any pathogen, research feature, or environment drives risk. For example, we can ask the specific question of how much does fatality risk change if one increased the transmissibility of H5N1 influenza in humans to half of that of seasonal influenza. We would explore how the probability and consequences of all laboratory accidents depends on this change, and how the probability of a local outbreak escaping control depends on this change and how the consequences of a global outbreak depend on this change. Comparing the three modeling components together provides an overall estimate of the change of risk.

In fact, for each pathogen phenotype and condition under which GoF research could be performed, we determined how varying the phenotype or research condition within scientifically defensible limits

influences risk. To undertake this sensitivity analysis, we determined how risk changes if a parameter value is held to a series of specific values in a Monte Carlo analysis in which other parameter values are allowed to be selected at random. This analysis determined if risk increases or decreases as any specific parameter value changes across the range of possible values for all other parameters.

Each parameter that is found to significantly influence risk (either positively or negatively) compared to a baseline that assumes work with unmodified pathogens was further explored to understand the reason behind this relationship. In this way, we determined if a parameter value must be set to an unreasonable value in order to significantly drive risk or if risk can be increased at parameter values that could be easily expected. Moreover, by analysis of the results, we determined if risk is driven only when a combination of parameter values occurs (for example, risk increases significantly only if the pathogenicity *and* transmissibility of an agent is increased, or only if transmissibility is increased and the work is performed without worker health monitoring). Together these results will help identify the GoF activities and conditions that could significantly increase risk of an outbreak compared to work with wild type pathogens.

The branching process model and the IIM are computationally intensive and so a Monte Carlo analysis could not be done to explore the entire parameter space. Instead, a variety of discrete parameter values were rationally chosen to defining the epidemiology (e.g., R_0 and latent period) of the viruses and the efficacy of control measures to contain the outbreak. For each of these parameters, a range of values believed to cover a significant fraction of the possible parameter values were used, and results were obtained for each unique combination of every parameter varied. Figure 6.12 illustrates the variation in simulation results for these parameters for seasonal flu global outbreaks, where each marker represents a result for a unique combination of parameters.

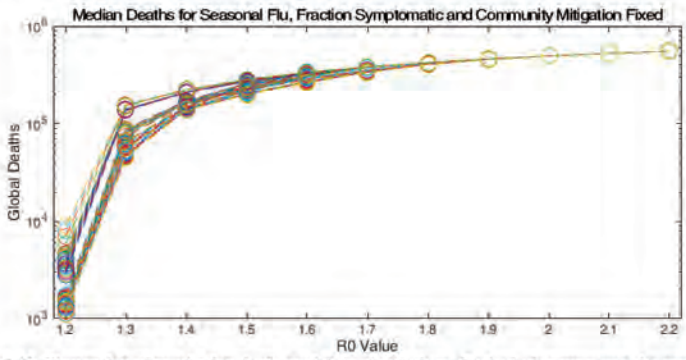

Figure 6.12. Illustration of results for single models in simulations. Each circle represents the results from a single model run with a single set of parameters. Lines connect models that differ only in the R0 value used in the simulation. To reduce the number of lines for visual clarity, some parameters were fixed: shown are models using the median values of antiviral efficacy on mortality, case fatality rate, and fraction of cases symptomatic, as well as no community mitigation; all other parameters ranged across their values appropriate for seasonal influenza.

Elsewhere in this report, when showing results for these simulations, the median number of deaths across all values of the varied parameters is shown by the marker, and the 10th and 90th percentile value of deaths across the same parameters are shown by vertical lines extending outward from those markers (the "error lines"). These vertical lines do not represent statistical (aleatoric) uncertainty in the underlying

simulations; instead they represent uncertainty as to the properties of the virus, outbreak and public health capacities (epistemic uncertainty). If a real-world outbreak were to occur with a defined set of parameters matching those simulated by one of the models, the results would, with high confidence, match those of that particular model. In addition, while these vertical lines plotted cover 80% of the resultant number of deaths for the model parameters simulated, they should not be understood as a typical 80% confidence interval. Because no probability distribution was assigned to the underlying varying parameters, the vertical lines represent *the middle 80% of the outputs of the simulations*, and not *the range of the 80% most likely outbreaks*. This approach suggests that a real outbreak would follow the overall shape of the median line presented (and not simply move randomly inside the range presented), but may be higher or lower (up to the bounds of the "error bars") if certain properties of the virus or the control measures caused the outbreak to spread more aggressively (or less aggressively) than the median set of parameters.

6.3 Practices in GoF Laboratories That Reduce Risk but Are Not Included in Our Study

To collect data to inform the modeling approach, interviews were conducted with laboratorians, biosafety officials, and public health officials. These interviews uncovered several measures that certainly reduce the risk posed by containment research but in ways that could not be included in a quantitative study that models human behavior abstractly. This section describes some of these practices that speak well of the culture of biosafety that exists in these containment laboratories but could not be captured by our models.

A thorough examination of current practices in influenza and coronavirus biosafety level 3 (BSL-3) was conducted through site visits and interviews with researchers, public health officials, and institutional representatives. Best practices in biosafety and biosecurity pertaining to Gain of Function research were identified that exceed recommendations or requirements from various bodies, including the Occupational Safety and Health Administration (OSHA), select agent regulations, recommendations of the Federal Experts Security Advisory Panel (FESAP), and Institutional Animal Care and Use Committees (IACUC). Practices either unique to specific institutions or commonly found across institutions are highlighted and were found to be especially beneficial/optimal/useful in training, exercises and drills, laboratory practices, health precautions, physical security, and institutional culture.

6.3.1 Training

Laboratory directors and personnel at various BSL-3 laboratories shared their protocols for training new researchers. From this, several best practices are highlighted. One observed prerequisite to BSL-3 work is demonstrating competency in BSL-2 work. Additionally, across all institutions, extensive BSL-3 training was observed, involving both written examinations and supervision of hands-on laboratory skills. One institution described a tiered training structure, in which the first tier covered basic laboratory operations, emergency situations, and general laboratory safety. The second tier covered more specific training for laboratory safety when performing cell culture work. The third tier covered procedures and precautions for animal work. Each tier was associated with a training checklist, which a trainer would use to assess the trainee. Another institution required the trainee to shadow the trainer in the BSL-3 laboratory and perform laboratory procedures under mentored supervision before conducting independent work. Best practices for hands-on training involve dedicated one-on-one instruction and active roleplay for scenarios such as an animal bite or a biohazardous spill.

Training and education can be codified into standard operating procedures (SOPs) covering experimental protocols, biohazardous spills, working with animals, potential exposure to infectious material, and biosecurity threats. These SOPs can be made easily accessible within the BSL-3 containment lab, should the need arise. Demonstrating knowledge of all SOPs can be required as part of BSL-3 training. Additional training in biosecurity is also recommended, covering topics such as cybersecurity, identifying

abnormal or suspicious behavior, identifying insider and outsider threats, and how to deal with strangers requesting lab access. Institutions remarked on the need for constant reminders and renewal of training to counter complacency. Commendably, some institutions were particularly thorough about BSL-3 training requirements. Visiting researchers were required to repeat BSL-3 training, even if they had prior experience either elsewhere or at that same institution. Training is not only limited to issues of biosafety and biosecurity. One institution provided communications training for researchers on how to discuss Gain of Function work in public settings. Finally, institutions can offer select agent training to first responders to inform what agents may be present during an incident and what to do in case of a large-scale spill or a fire.

6.3.2 Exercises and Drills

Hands-on training can extend beyond laboratory protocols to tabletop exercises and drills within and outside the laboratory setting. Institutions described several exercises and drills, such as responding to a researcher having a medical emergency in the BSL-3 containment lab, responding to a potential exposure in the laboratory, and responding to a natural disaster. Another research facility discussed methods for testing their security infrastructure, such as leaving a door open or holding up signs to security cameras to test for prompt response. On a wider scale, the research institution can conduct exercises and drills in conjunction with first responders, environmental health and safety (EHS), and local hospitals for better preparation against a potential exposure. Examples of such exercises are: a researcher following SOPs for exposure to a pathogen, a researcher not following SOPs for exposure and showing up at a hospital emergency room, and response to a bomb threat. Conducting these drills also strengthens cross-institutional relationships, which can better inform future preparedness and response protocols. One institution asked local first responders to perform walkthroughs of the research facility to learn how to gain access and what to do during an emergency. For instance, the fire department was instructed to contain but not extinguish a fire in the BSL-3 containment lab, allowing it to burn within those boundaries. Notably, one institution remarked that whenever a researcher would display influenza-like illness, this essentially became an exercise in practicing SOPs for a potential exposure. Finally, a best practice that formalizes these relationships is to establish an Emergency Operations Center (EOCs) under the parent institution or university to better coordinate emergency responders, EHS, local public health, and the research facility. EOCs can run campus-wide drills to scenarios such as bomb threats, natural disasters, and active shooters to prepare a coordinated response effort from multiple agencies.

6.3.3 Laboratory Practices

CDC select agent regulations dictate several requirements for day-to-day laboratory operations, including a regular inventory of pathogen stocks and inspections of laboratory equipment and the BSL-3 facility. Several institutions have demonstrated particularly useful laboratory practices that may surpass regulatory requirements or otherwise represent optimal biosafety and biosecurity measures in access control, inventory, animal work, facility maintenance, and communications. Furthermore, select agent requirements represent best practices for non-select agent labs that work with, for instance, seasonal influenza viruses.

Several best practices in access control are highlighted here. One non-select agent status laboratory was observed to keep its freezer containing pathogen stocks under lock and key and to perform frequent inventory checks. Another practice was to grant access to select agent freezers only to a small number of staff out of the many more who were approved for BSL-3 work. This can prevent researchers from performing unauthorized experiments, as it requires explicit permission to access the pathogen stocks. Another institution required researchers to obtain permission to access anesthetic drugs for anesthetizing

animals for *in vivo* work. More broadly speaking, it would be a best practice to control access to reagents necessary for risky experimental protocols.

Maintaining an updated inventory is a requirement for laboratories working with select agents. However, one institution was noted to count inventory more frequently compared to peer institutions (monthly instead of quarterly). Alternatively, another facility performed random inventory checks. One institution randomly sampled 10% of its boxes to reconcile its contents with the inventory log. If discrepancies were noticed, a 100% inventory check was performed, and the CDC was notified. Another select agent requirement is to limit how long experimental samples may be kept. The best practice observed for this requirement was to keep experimental samples up to 30 days, after which they were either discarded or added to the permanent inventory. There are several additional best practices associated with counting inventory. One institution required two people present to count inventory. One researcher was "permanent" and was always present at every inventory check. The other researcher was "rotating" to witness the inventory count and ensure that inventory was not simply memorized as a complacent way of counting. Another institution assigned one employee to keep track of all changes to inventory; this employee was responsible for conducting counts and was to be notified if a sample were to be taken from stocks.

Additional practices were noted that improve the safeguarding of inventory. Witnesses can be required for any changes to inventory, including taking agents from pathogen stock, destroying old samples, and adding samples. Stocks not used for at least one year can be archived in boxes sealed with security tape.

Researchers highlighted several best practices when working with animals in the course of pathogenic research. One is to limit researchers' and animal caretakers' contact with laboratory animals, a USDA regulation though not a CDC regulation. Animals can be observed prior to the conduct of experiments to determine whether they are prone to abnormal or aggressive behaviors, which may make them more likely to inflict bites or scratches on their handlers. These behaviors will be noted for experimenters so they can take appropriate precautions when working with those animals. Furthermore, animals can be completely or partially anesthetized before experimental procedures to prevent bites or scratches. One research group noted that genetically mixed mice were more prone to aggressive behaviors and thus partially anesthetized all mixed mice as a precaution. A daily check, including weekends and holidays, of animals and other laboratory equipment can be conducted. In order to record which employees were trained to perform animal experiments, animal husbandry, and respiratory testing, one facility kept an animal handling training sheet. Finally, a paper trail for each laboratory animal can be maintained, which details its history of procedures, tests, and bodyweight measurements, as well as the dosage and strain of the experimentally induced infection.

Briefly, some best practices were noted with regards to maintaining the facility and its equipment. Frequent inspections of the shower and facilities can ensure that containment safeguards and decontamination procedures remain optimal. Additionally, several facilities performed annual shutdowns for several weeks in order to perform a comprehensive surface and gas decontamination and to perform preventive maintenance.

There were several practices observed that sought to optimize researcher-to-researcher communications or to utilize a partner system to limit mistakes or malicious behavior. A radio system can be used to communicate between BSL-3 researchers and outside staff. One institution mandates that any potential exposure, no matter how minor and even if it does not breach PPE or skin, should be reported over the radio. This allows an outside employee to be aware of the situation, and furthermore the employee can guide the BSL-3 researcher on next steps, preventing a possibly stressed researcher from making rash decisions. Another simple tool is to place a whiteboard outside the BSL-3 containment lab that displays which researchers are working in which suites, and which pathogens are in each suite. One best practice

that was especially notable was notification of weekend or after-hours work. Researchers seeking to conduct work off-hours can be asked to notify a coworker by phone of time of entry, expected duration, and time of exit. One institution employed an on-call cell phone, which is always kept on and is assigned to an employee by rotation. Messaging this phone is required for after-hours work in the laboratory. Finally, several institutions require BSL-3 laboratory staff to wear emergency "man-down" pendants, which can used in the event of an emergency to alert first responders and research supervisors.

With regards to a partner or two-person system, when interviewing different research institutions, different opinions emerged on its utility. Many institutions required the partner system when performing experiments requiring animals or sharps. Some institutions used the partner system liberally, requiring witnesses to validate changes to inventory (as mentioned above) or proper execution of inactivation protocols (inactivating an agent to transfer from BSL-3 to BSL-2). However, institutions differed in their opinions about the partner system when performing more routine experiments. One institution encouraged the partner system whenever possible. However, researchers at another remarked that the risk of accidental exposure was higher with two people, and that the two-person system provided little utility. It is important to point out that the utility of the two-person system has historically been contentious, and that no applied research has been done to assess the benefit of such a measure.

Lastly, some additional best practices for day-to-day laboratory conduct are to limit a researcher's hours in a BSL-3 lab to three to four hours daily and to designate one employee to receive and sign off on shipped biological materials. These can limit the chance of exposure and ensure an extra degree of security, respectively.

6.3.4 Health Precautions

Several best practices were identified that better reduce the chances of severe illness following a laboratory exposure. These can be categorized as conditions of employment, post-exposure SOPs, and partnerships with local and state public health departments and with local hospitals.

Some institutions were observed to require employees who worked in BSL-3 laboratories to abide by certain rules. One commonly observed best practice was the requirement of the seasonal influenza vaccination as a precaution against laboratory-acquired influenza infection. Another was to medically clear new employees, which would (1) discover any underlying medical issues that may exclude a researcher from working with select agents and (2) obtain a baseline serum sample prior to starting lab work, in order to test for seroconversion in the event of potential exposure. Lastly, one institution obtained signed statements from its employees agreeing to self-quarantine, self-report body temperature, permit home visits by a nurse, and submit samples for diagnostic testing, in the event of a potential exposure.

One best practice for post-exposure SOPs is to include extra precautions following a potential exposure. For instance, one institution isolates the exposed researcher and administers an N95 mask without an exhalation valve while awaiting emergency medical response, even though the pathogen would not be expected to replicate within those few hours following exposure.

Partnerships between the research institution, local and state public health, and local hospitals can be established prior to an exposure incident to expedite the medical response. Researchers can carry cards describing their occupation and what agents they work with, which should be shown at the emergency department to facilitate proper treatment. Medical emergency protocols for laboratory pathogens used in the neighboring research institute can be shared with the local emergency department, and occupational health concerns for working with these pathogens can inform hospital protocols for safety and security. In

fact, this can be further codified into a memorandum of understanding (MOU) with the local hospital. It was noted that if the institution is a university, hospital physicians can often be affiliated with the university's medical school, which facilitates a culture of cooperation between the hospital and research staff. The contributions of institutional culture to best practices in biosafety and biosecurity are explored in a later section. Finally, one institution has shared samples and genomic sequences with the state public health department to verify that their diagnostic tests detect the virus strains commonly used in the laboratory, in the event of a potential laboratory-acquired infection.

For employees leaving the university, they must terminate access two weeks prior to leaving and go through an exit physical before they leave, to ensure they're not sick (two weeks based on incubation period of SARS/MERS – ten days). In some laboratories, everyone must check into lab daily. If someone doesn't show up, the lab is responsible for tracking them down. Lab will notify EHS if they are unaware of someone's whereabouts, and EHS will reach out to the university hospital ER to let them know to watch out for that person to show up.

6.3.5 Institutional Culture

Several researchers cited their institutional culture as a powerful factor in promoting safety and security in the laboratory. Institutional culture can dictate workplace satisfaction, willingness to report incidents, awareness, and workforce turnover, all of which can directly or indirectly influence the levels of biosafety and biosecurity. Several institutions noted the importance of developing a non-punitive culture that encouraged over-reporting, especially of "gray-area" incidents such as a minor spill without breach of PPE or skin. Also widely practiced was a culture of carefulness and vigilance, bolstered by consistent reminders to practice good safety and security measures to prevent complacency. One institution remarked that the principal investigator sets the example by obtaining all biosafety and biosecurity training. Many institutions cited their small work environment as conducive to maintaining vigilant security, since all of the staff knew each other. One supervisor commented about developing an intuition for the happiness levels of all staff members, which can reduce the risk of an insider threat. Institutions can additionally offer assistance programs for employees to cope with hardships or obtain counseling. Establishing an environment that promotes staff retention is also a best practice. This builds relationships between laboratory staff and is a strong security measure in limiting the number of new employees. Additionally, one institution does not allow undergraduate students to work in the BSL-3 lab, due to concerns with turnover and with the length of time needed for BSL-3 training.

Strong support from the parent institution for the Gain of Function research program can also promote a positive working culture. One research group noted that, in the face of controversy, the parent institution remained strongly supportive of the research program, which encourages the laboratory staff to be diligent about reporting incidents and maintaining a safe and secure working environment.

Finally, as mentioned above, strong relationships between the research institute and local hospitals, first responders, regional FBI offices, EHS, and local and state public health departments contribute to a positive institutional culture that lends itself to better preparation for and response to laboratory incidents.

6.3.6 Additional Institutional Policies

Finally, additional best practices were observed in various institutions that do not fall under the above general categories. Several institutions required principal investigators to register their research with EHS, documenting a notice of intent (listing the agent of study, purpose of the study, and dual use research questions), a risk assessment, and training requirements. As part of this registration, EHS can perform an annual inspection of the facilities to verify the proper safety and security measures. Institutions have also

employed campus-wide behavioral risk assessments to monitor for behaviors or emails of concern. Finally, institutions can share their own practices with other research facilities, improving each other's security and safety procedures.

6.4 Probability of Laboratory Acquired Infections

6.4.1 The Selection of Incidents to Include in the RBA

In this study, we analyzed ten previous laboratory accident risk assessments and three compilations of accident/incident reports to identify the accident or incident scenarios that would be quantitatively evaluated in our study. Any scenario that was high risk (either due to their frequency or consequence) or used as the "maximum reasonably foreseeable events" in *at least* one source was included for quantitative analysis, except when:

- General accident types that are explored in more detail by another accident type (e.g., "waste stream" would be discarded in favor of the high risk "leaking pipe" scenario),
- Any incident with an unknown cause because these are not quantifiable (e.g., "contamination outside laboratory with unknown cause"—note that these are likely captured by other event types), and/or
- Accidents specific to containment research on large animals

Other scenarios were considered but not included in a quantitative analysis because they are rarer than events that would have a larger consequence. Beyond these events, we included additional scenarios to capture risks that may inhere in GoF research specifically or were recently in the news, specifically:

- Floods, due to the flooding of hospitals and laboratories that occurred during Hurricane Sandy, and
- Animal bites because of extensive work with ferrets, which tend to bite more often than mice or guinea pigs

In many cases, the "incidents" identified in other reports aren't incidents in themselves but risk factors that influence the risk of other incidents. That is, if the HVAC system fails, this failure has a consequence only if animals are actively exhaling pathogen into the ambient air or there is a spill or splash. For these events, their probability of occurrence was included in ALL other relevant accident fault trees. In total, 16 incidents were investigated in detail to form the basis of our quantitative analysis.

Table 6.1. Rationale for Scenarios Included in the Risk Benefit Assessment.	
Scenario	**Rationale for Inclusion**
Splash incident	Recognized as high risk in the NBAF
Spill incident	Recognized as high risk in NBAF
Failure to keep containment in place	Recognized as high consequence in NEIDL. Included as a factor in other incidents
Solid waste incident	Recognized as high risk in NBAF
HVAC failure	HVAC failure was noted in reports and could be of potential high consequence. Included as a factor in other incidents
Equipment-- failure of containment feature	Common in incident reports. Included as a factor in other incidents
Equipment--power loss at facility	NEIDL estimates high risk and actual examples in reports
Improper inactivation of pathogen	Many examples in reports, human error (with equipment failure, human failure to check inactivation (e.g., recent anthrax at DoD)). Investigated separately but also is part of other incidents investigated (waste streams and splashes).
Transference--glove to skin due to improper removal	High risk in NBAF. Included as a factor in other incidents
Shipping accident	Considered exceptionally high risk in NBAF; examples in reports of accidents (though of no consequence)
Animal--escape from containment	Recognized as high risk in the NEIDL while other RAs state low risk; some examples in literature of animals escaping or otherwise disappearing
Improper inactivation of liquid waste	Recognized as high risk in NEIDL
Centrifuge release	Canonical high risk scenario in almost every RA
Natural Disaster--earthquake	Most catastrophic scenario for NBAF and NEIDL
PPE Failure	Several examples in literature leading to actual laboratory acquired infection
Protocol failure--use of wrong containment	Several examples in literature leading to actual LAI. Included as a factor in other incidents
Puncture/sharp object injury	Puncture is the most common cause of reportable lab accidents. Because the GoF pathogens are probably not infectious via injection, this incident is considered to lead to a breach in the gloves that creates a contamination on the hands (leading to possible later inoculation of the worker or a contact).
Waste-liquid waste leak/pipe burst	High risk in NEIDL
Animal--bite/scratch	Although low risk in NEIDL, may be higher frequency in ferrets
Exhaled pathogen escapes laboratory (animal respiration)	Due to contagious nature of some GoF pathogens, this scenarios deserves quantitative evaluation
Natural Disaster--flood	Low risk but recent examples present - Galveston and New York
Scenarios listed in blue are failure modes that could exacerbate the risk of a loss of containment and are included in other events. Scenarios listed in green were included by name in this assessment.	

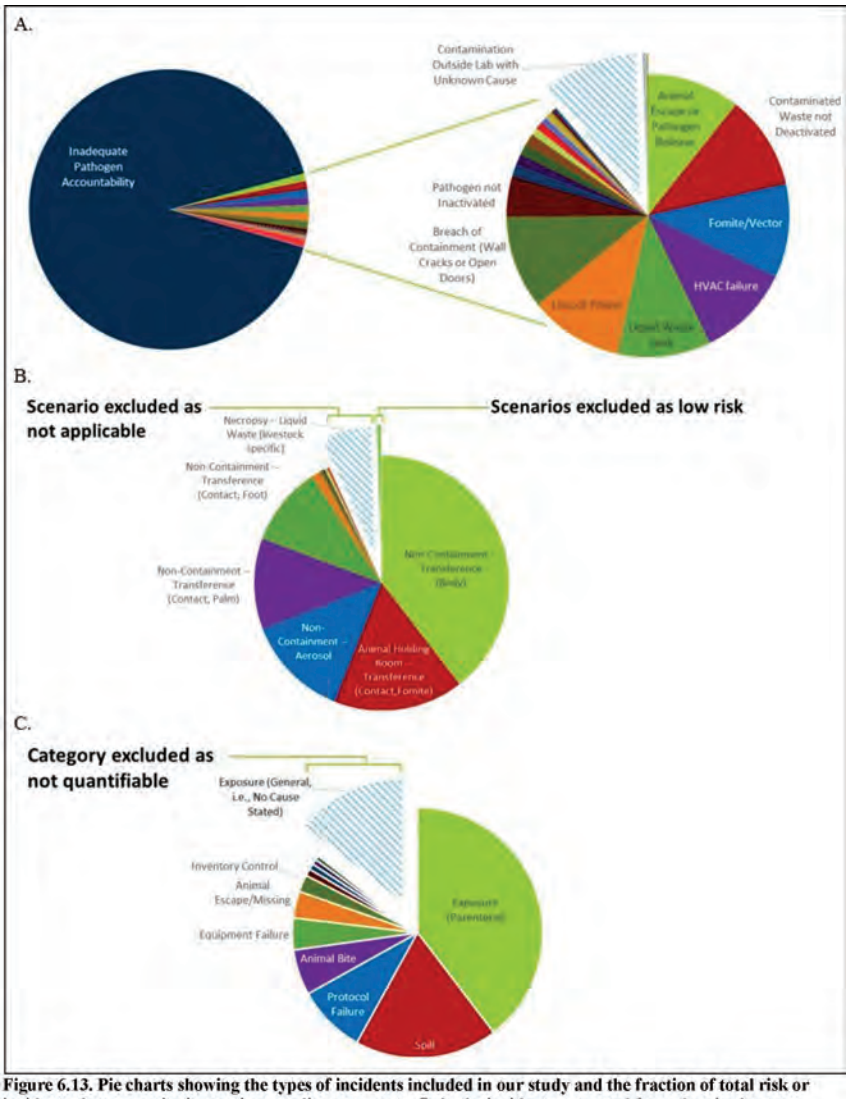

Figure 6.13. Pie charts showing the types of incidents included in our study and the fraction of total risk or incidents they comprise in previous studies or reports. Only the incidents extracted from the pie chart are excluded from further analysis in this RBA. A. The NEIDL, B. The NBAF, C. past reports.

Note that these events include the low probability, high consequence incidents; the high probability, high consequence incidents; and the high probability, low consequence incidents from other reports, along with the "maximum reasonably foreseeable events" incidents. Excluded from this point on in the assessment are only the events that are rare and inconsequential, or not foreseeable (for instance, have a probability of less than the age of the earth). Note, any event that is reasonably foreseeable (even if extremely unlikely) and of high consequence was captured in our assessment. These 16 incidents capture the vast majority of the risk from previous assessments: more than 99% of the risk from the NIEDL study, about 90% of the risk from the NBAF study (much of the rest relates to work with large animals only), and 80% of incident reports (the rest are not quantifiable due to unknown cause) (Figure 6.13 above).

All incidents included in our study were studied to reconstruct the pathways leading to the loss of containment event. After study, some incidents were excluded from quantitative analysis because no plausible scenario that leads to a loss of containment could be identified to model. Other incidents were quantitatively investigated but excluded from the fault tree analysis because all pathways identified lead to vanishingly unlikely and/or small releases. See Appendix III for details.

6.4.2 Identification of Locations at Risk of Earthquakes and Floods

To quantitatively assess the risk of earthquakes and floods at GoF laboratories, we found the GPS coordinates of 36 containment laboratories, including labs that were formerly conducting GoF research and several additional BSL-4 and BSL-3 facilities that are currently operational or under construction. The flood risk at each location was assessed using information from the Federal Emergency Management Agency.[359] The earthquake risk was assessed using information from the US Geological Survey.[360] Of these 36 locations we identified the locations of greatest risk of flooding and earthquake and assessed the risk of a loss of containment event at that facility due to a natural disaster. If the risk was significant, we would have assessed the risk from these natural disasters at other sites with slightly lesser risk. However, we found that the risk of natural disasters was minor compared to accidents, so this analysis was not performed.

6.4.3 Irreducible Uncertainty Prevents an Accurate Prediction of Absolute Risk

Humans are an integral component of every laboratory, however, humans are prone to making mistakes due to carelessness, haste, tiredness or unfamiliarity with validated procedures. In most complex systems, the physical systems (fans, valves, filters, alarms) are demonstrated to fail much less often than the humans operating the systems and interpreting the alarms these systems make when an error occurs. The only human reliability data found directly related to work in a containment laboratory are studies of decontamination (when removing gloves or washing hands). Much of the data on human reliability comes from the transportation, chemical and nuclear sectors and this study had to analogize to interpret human error rates to laboratory situations. Because of the absence of data, in this risk assessment some conservative assumptions were made that prevent the accurate estimation of absolute risk. None of these assumptions affect the relative risk of an accident with a modified pathogen compared to a wild type and so the comparative risk assessment still holds.

Conservative assumptions made include:

---

[359] FEMA, National Flood Hazard Layer Map (Official), accessed in June, 2015 at http://fema.maps.arcgis.com/home/webmap/viewer.html?webmap=cbc088e7c8704464aa0fc34eb99e7f30.

[360] USGS, US Seismic Design Maps, accessed in June, 2015 at http://earthquake.usgs.gov/designmaps/us/application.php

- When a skill error (a slip) happens with a sharp object (scissors, typically) during a necropsy, the assumption is that the slip results in a cut through the worker's glove(s). There are no data on the relative number of errors during necropsy that result in damage to the specimen, dropping of the instrument or any other inconsequential failure compared to breaches in the gloves, therefore this assumption was made to conservatively maximize risk.

- When a splash happens when working with pathogen (for example a contaminated pipette tip skipping over the top of a well), the splash is assumed to land on the worker's hands and not the hood or any part of the clothes or body unlikely to contact the worker's face or others outside the laboratory. There are no data on distribution of drops from laboratory accidents on this scale so the assumption of contamination on the gloves was made to conservatively maximize risk.

- When a worker contaminates their hands by any pathway, the contamination is assumed to be on the fingertips because this part of the hand is mostly likely to contact a contaminated surface. This is a conservative assumption because the fingertips are the only part of the hand to permit a self-inoculation (in the eye or nose) to maximize risk.

- When gloves fail, they are assumed to fail on the fingertips because these parts of gloves are the most prone to failure. Note that this assumption forces the point of contamination and glove failure to be coincident, which maximizes risk.

- When an accident the worker directly caused leads to the generation of an aerosol (like the spill of a viral stock), the assumption is made that the worker inhales all of the aerosolized pathogen because they are nearest to the most concentrated part of the spill (assuming that the aerosol reaches equilibrium in the room does not account for the fact that the worker was relatively close to the source).

6.4.4 Relative Probability of Laboratory Acquired Infections

The approach used in this risk assessment predicts that a variety of accidents, when combined with human or equipment failures, lead to laboratory acquired infections from work with the GoF pathogens. For seasonal influenza, most laboratory acquired infections are the result of aerosols accidentally generated by spills or centrifuge accidents, while a minority are caused by contamination of the hands during necropsy, cell culture, or via an animal bite. For pandemic influenza, because of the additional respiratory protection used under BSL-3 conditions, events that contaminate the hands cause slightly less than half of the laboratory acquired infections, while the rest are caused by aerosols. In avian influenza laboratories, the vast majority of infections are those of wild birds contaminated by the accidental discharge of incompletely decontaminated solid waste. Less than 10% of the accidental infections caused in avian influenza laboratories are in the human workers. For the coronaviruses, even though additional respiratory protection is worn under BSL-3 conditions, most infections are caused by aerosol exposure because other routes are unlikely to cause an infection. Although this analysis produces a robust estimate of relative risk in a variety of informative ways, the data used are insufficient to predict absolute risk. A separate method is used to support a rough estimate of absolute risk in Section 6.8.

In sum, the analysis of these release pathways enables the estimation of the relative risk of working with the GoF pathogens and how the change of any phenotype would alter this risk. Table 6.2 shows the relative probability (compared to work with seasonal influenza) of a laboratory acquired infection (that produces some hazard of a causing a local outbreak) when working with the various pathogens considered in this study. Our analysis considers that vaccination of laboratory workers could reduce the chance of a laboratory infection and that antivirals could be given prophylactically if a high risk exposure event

occurs. Moreover, health monitoring and isolation protocols would greatly reduce the chance that a worker mingles with the general population, causing secondary cases and sparking an outbreak. In this section, these factors are always considered when examining the pathways that lead to a laboratory acquired infection, because if the infected worker poses no hazard to the population, the consequences of the accident end with that person.

Table 6.2. Relative Probability of a Laboratory Acquired Infection for the Various Pathogens Considered in This Study as Compared to Work with Seasonal Influenza

Pathogen	Biosafety Level	Relative Probability of an LAI*
Seasonal influenza virus	BSL-2	1 (defined)
Pandemic influenza virus	BSL-3	0.10 (0.07-0.15)
Avian influenza virus	BSL-3	0.43 (0.21-0.90) (mostly of birds)
SARS-CoV	BSL-3	0.03 (0.02-0.04)
MERS-CoV	BSL-3	0.01 (0.006-0.02)

These data are generated by comparing the sums of the frequency of infection from all loss of containment pathways for each pathogen. In this case, we use the term laboratory acquired infection to include an infection of wild birds to capture the comparative risk of working with avian influenza viruses. The numbers in the parenthesis are the results from the p5 and p95 outputs of the Monte Carlo analysis.

The irreducible uncertainty in the pathways that lead from laboratory incidents to infections of wild birds with avian influenza is evident in these results. As will be described below, if infected material leaves the laboratory, it is assumed that wild birds will access it at the dump because there is no way to estimate what percent of bags are accessed by birds in a dump. The estimate here is therefore conservative but, even with the uncertainty provided, suggests that the probability of a wild bird becoming infected in a laboratory accident with avian influenza is roughly equivalent (within an order of magnitude) to the probability a person will be infected by a laboratory accident involving seasonal influenza. In contrast, the risk of an accident leading to an infection with any other pathogen is roughly one (for pandemic influenza) or two orders of magnitude less (for the coronaviruses).

The sections that follow explore the various pathways that lead from a laboratory accident to a laboratory acquired infection for each of the pathogens examined. The relative probability of laboratory acquired infections when working with pathogens with GoF phenotypes compared to the work with wild type pathogens is described.

6.4.4.1 Laboratory Acquired Infections and Seasonal Influenza

When working with seasonal influenza under BSL-2 conditions, the accidental generation of aerosols produces the majority of laboratory acquired infections because no personal respiratory protection is worn (and the agent is extremely infectious). Only a small minority of accidental infections are caused by the contamination of the hands. Figure 6.14 shows the various accident pathways that contribute to the probability of a laboratory acquired infection. Data in these figures comes from comparing the total frequencies of laboratory acquired infections, which in turn is derived from the predicted frequency of exposure events with various pathogen amounts as calculated by the Fault Tree Models. Comparing the 5th, 50th and 95th percentile[361] of our Monte Carlo simulations suggests that changes in risk of less than a factor of two are not that significant because the total probability of an infection from any cause changes

[361] Recall that the p50 is the median result, whereas the p95 is the result in which 95% of all results have a smaller value, and the p5 is the result in which 5% of all results have a smaller value.

by this much between the samples (relative to the p50, the p5 is 2.3-fold less and the p95 is 1.6-fold greater). In terms of the incidents that contribute to the probability of infection, the 5th and 95th percentile results are similar to the p50 but the fomite-based pathways contribute to the infections slightly more frequently (splashes cause from 0.5 to 3% of infections and cuts cause from 0.8% to 10% of infections depending on the sample).

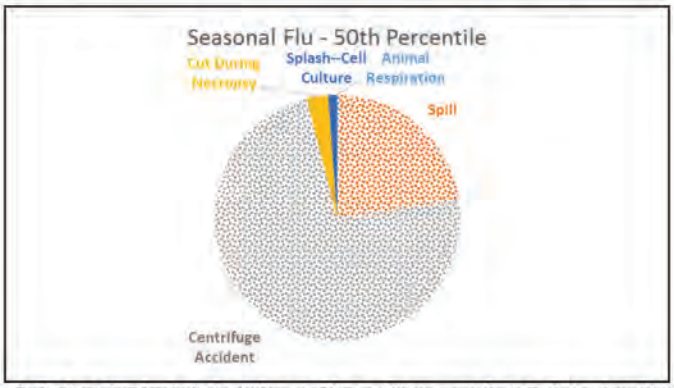

Figure 6.14. A pie chart showing how the various accident pathways contribute to the total probability of a laboratory acquired infection for seasonal influenza. Solid colored sections are fomite-based hazards, hatched sections are aerosol-based hazards and stippled sections are both fomite- and aerosol-based hazards. The median result of the Monte Carlo analysis is shown.

Some of the GoF phenotypes could affect risk of a laboratory infection (Table 6.3). Viruses that grow to a high titer could increase the dose received by a victim via an aerosol or fomite-based exposure and approximately double the chance of a laboratory acquired infection if cultures with these high titers are routinely manipulated. That being said, many strains of seasonal influenza already grow to a titer of 1E8/ml and increasing this titer may not be desirable or scientifically achievable. The strain could be made antiviral resistant, which would vitiate providing antivirals after a high-risk exposure. Similarly, the strain could be made to evade the protection afforded by vaccines. Because seasonal influenza is already adapted to humans, this GoF phenotype is not relevant for this pathogen. Table 6.3 shows the relative increase in the probability of a laboratory acquired infection predicted if modified strains of seasonal influenza are created. As titer increases, splashes begin to contribute more to the risk of a laboratory acquired infection, but still contribute less than 20% of the total risk (not shown).

Table 6.3 Increase in the Probability of a Laboratory Acquired Infection Associated with GoF Phenotypes in Seasonal Influenza	
Phenotype	**Increase in Probability of a LAI**
Evasion of vaccines	+50%
Antiviral resistance	+40%
Growth to 1E9/ml	+100%
Growth to 1E10/ml	+140%
Adaptation to humans	N/A

6.4.4.2 Laboratory Acquired Infections and Pandemic Influenza

When working with pandemic influenza under BSL-3 conditions, the accidental generation of aerosols produces the majority of laboratory acquired infections even though personal respiratory protection is worn. About 20% of accidental infections are caused by the contamination of the hands. This finding holds across the p5 and p95 samples (although in the p95 the fomite-pathways contribute to ~30% of risk) Figure 6.15 shows the various accident pathways that contribute to the probability of a laboratory acquired infection.

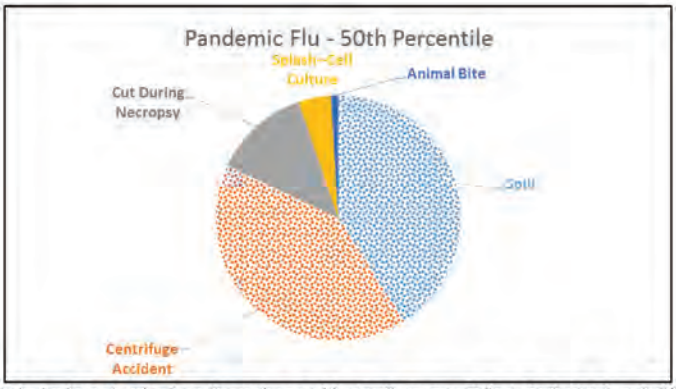

Figure 6.15. A pie chart showing how the various accident pathways contribute to the total probability of a laboratory acquired infection for pandemic influenza. Solid colored sections are fomite-based hazards, hatched sections are aerosol-based hazards and stippled sections are both fomite- and aerosol-based hazards. The median result of the Monte Carlo analysis is shown.

Some of the GoF phenotypes could affect risk of a laboratory infection. Viruses that grow to a high titer could increase the dose received by a victim via an aerosol or fomite-based exposure. The strain could be made antiviral resistant, which would vitiate providing antivirals after a high-risk exposure. Similarly, the strain could be made to evade the protection afforded by vaccines. Because pandemic influenza is already adapted to humans, this GoF phenotype is not relevant for this pathogen. Table 6.4 shows the relative increase in the probability of a laboratory acquired infection predicted if modified strains of pandemic influenza are created. Enhancing the growth of pandemic strains to achieve titers of 1E9 or 1E10/ml can significantly increase the risk that a laboratory acquired infection would occur because the exposures that drive risk are normally very low. That being said, some strains of pandemic influenza already grow to a

titer of 1E8/ml and increasing this titer may not be desirable or scientifically achievable. Increasing the maximum titer of poor growing strains to 1E8/ml simply allows these strains to approach the risk modeled for the more robust strains.

Table 6.4 Increase in the Probability of a Laboratory Acquired Infection Associated with GoF Phenotypes in Pandemic Influenza

Phenotype	Increase in Probability of a LAI
Evasion of vaccines	+50%
Antiviral resistance	+40%
Growth to 1E9/ml	+90%
Growth to 1E10/ml	+520%
Adaptation to humans	N/A

6.4.4.3 Laboratory Acquired Infections and Avian Influenza

When working with avian influenza under BSL-3 conditions, the accidental release of improperly decontaminated solid waste drives the risk of an accidental infection, albeit of a wild bird, not a human. In these cases, the operator committed an error, such as packing the autoclave too tightly with bedding-containing cages or carcasses such that the steam did not penetrate into all parts of the waste. Alternatively, the operator could run an improper cycle such that the temperature was not reached for the required length of time. The waste then enters the solid waste stream and is dumped, whereupon wild birds (like gulls that frequent garbage dumps) access the infectious material and are infected. Data is lacking to determine the percent of waste containers actually accessed by gulls, or even how an outbreak would unfold if gulls that live in garbage dumps were infected; however, the analysis assumes that an avian outbreak would occur with attendant human infections and deaths from exposure to infected wild or domestic birds. Direct infections of workers in the laboratory represent less than 25% of the probability of an infection. Figure 6.16 shows the various accident pathways that contribute to the probability of a laboratory acquired infection.

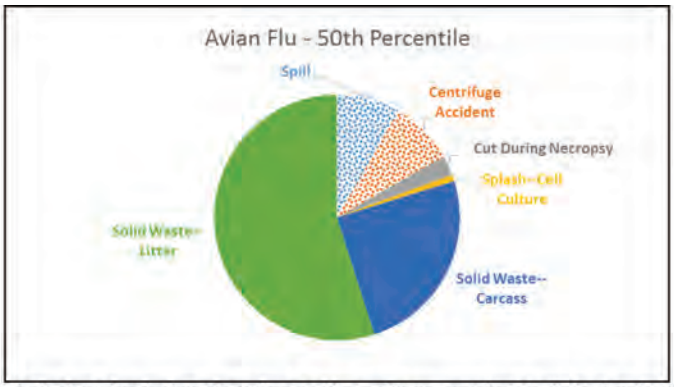

Figure 6.16. A pie chart showing how the various accident pathways contribute to the total probability of a laboratory acquired infection for avian influenza (including infections of wild birds). Both solid waste pathways infect wild birds only, and not humans. Solid colored sections are fomite-based hazards, hatched sections are aerosol-based hazards and stippled sections are both fomite- and aerosol-based hazards. The median result of the Monte Carlo analysis is shown.

The differences between the p50 and p5 result illustrate some of the significant uncertainty of the causes of accidents when working with avian influenza viruses (Figure 6.17). Although the pathways that lead to infection of a laboratory worker (compared to a bird) begin to contribute more to the probability of accidents, these pathways still contribute to a minority of infections.

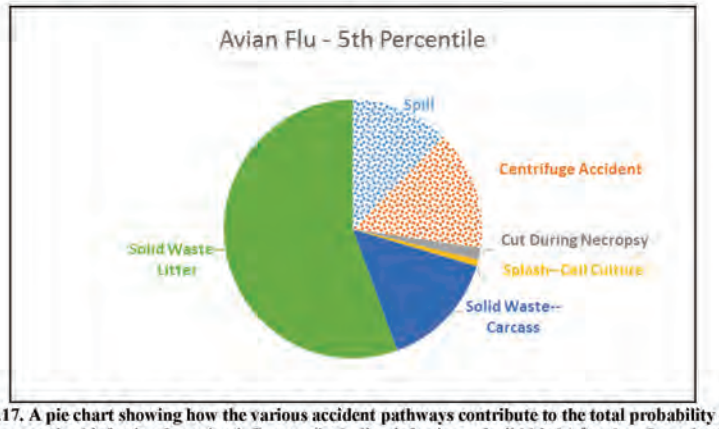

Figure 6.17. A pie chart showing how the various accident pathways contribute to the total probability of a laboratory acquired infection for avian influenza (including infections of wild birds) for the p5 result of the Monte Carlo analysis. Both solid waste pathways infect wild birds only, and not humans. Solid colored sections are fomite-based hazards, hatched sections are aerosol-based hazards and stippled sections are both fomite- and aerosol-based hazards.

Some of the GoF phenotypes could affect risk of a laboratory infection. Viruses that grow to a high titer could increase the dose received by a victim via an aerosol or fomite-based exposure. The strain could be made antiviral resistant, which would vitiate providing antivirals after a high-risk exposure. Similarly, the strain could be made to evade the protection afforded by vaccines. If the strain were adapted to humans, we assume it would poorly infect birds but would greatly decrease the infectious dose in humans. Table 6.5 shows the relative increase in the probability of a laboratory acquired infection predicted if modified strains of pandemic influenza are created. No GoF phenotype increases the risk that an accidental infection occurs with the avian influenza viruses, because so much of the risk of an accidental infection wild type pathogen is driven by the infection of birds from solid waste (all the GoF phenotypes affect the human health risk). In fact, adapting the strain to humans DECREASES the probability that a laboratory accident will lead to an infection of an animal or person by 30% because although the strain is more likely to infect a person, it is much less likely to lead to a dangerous outbreak in birds, which can sicken much more than a handful of laboratory workers. Note, because this analysis considers one GoF trait at a time, the adaptation to humans is assumed to create a strain that is more infectious in humans but not alter its transmissibility.

Table 6.5 Increase in the Probability of a Laboratory Acquired Infection Associated with GoF Phenotypes in Avian Influenza

Phenotype	Increase in Probability of a LAI
Evasion of vaccines	+11%
Antiviral resistance	+8%
Growth to 1E9/ml	+20%
Growth to 1E10/ml	+120%
Adaptation to humans	-30%

Figure 6.18 shows the accident pathways that lead to human infections for avian influenza strains adapted to infect humans (instead of birds).

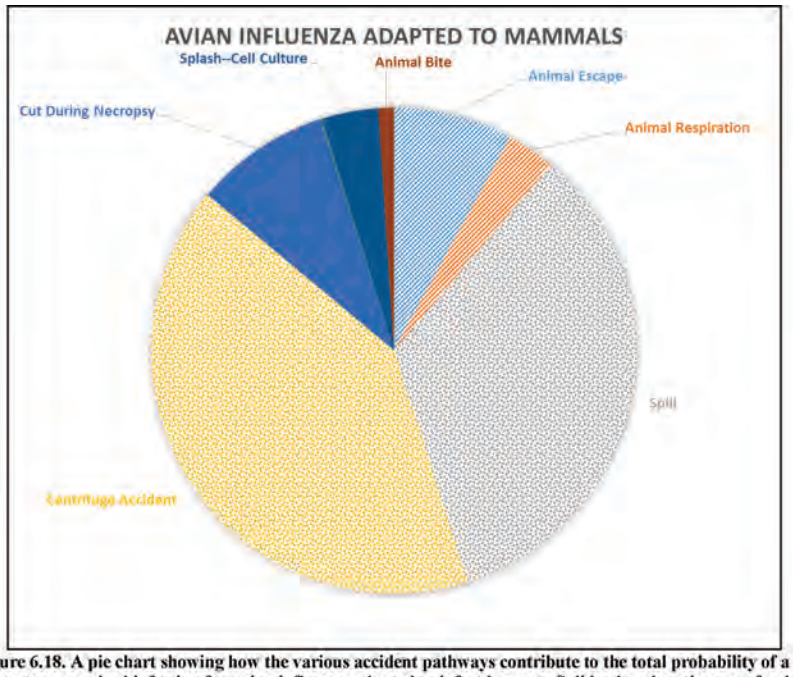

Figure 6.18. A pie chart showing how the various accident pathways contribute to the total probability of a laboratory acquired infection for avian influenza adapted to infect humans. Solid colored sections are fomite-based hazards, hatched sections are aerosol-based hazards and stippled sections are both fomite- and aerosol-based hazards. The median result of the Monte Carlo analysis is shown.

6.4.4.4 Laboratory Acquired Infections and Coronaviruses

When working with the coronaviruses under BSL-3 conditions, the accidental generation of aerosols produces the vast majority of laboratory acquired infections even though personal respiratory protection is worn. Working with infected animals poses minimal risk because mouse adapted strains poorly infect human cells due to changes in the spike protein. Figure 6.19 shows the various accident pathways that contribute to the probability of a laboratory acquired infection, the p5 and p95 results from the Monte Carlo analysis are similar (not shown).

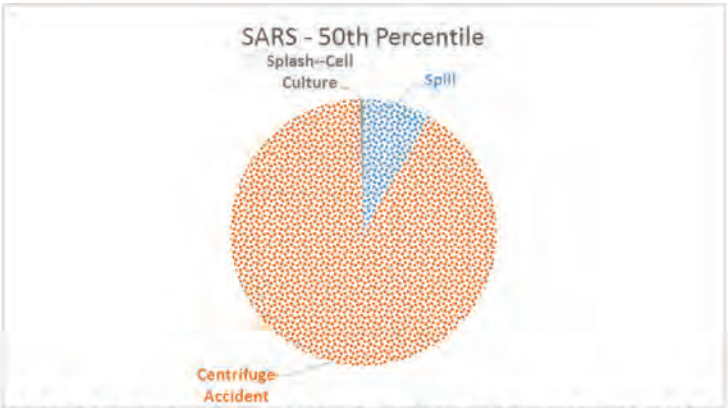

Figure 6.19. A pie chart showing how the various accident pathways contribute to the total probability of a laboratory acquired infection for SARS-CoV (the chart for MERS-CoV is very similar). Solid colored sections are fomite-based hazards, hatched sections are aerosol-based hazards and stippled sections are both fomite- and aerosol-based hazards. The median result of the Monte Carlo analysis is shown.

Only one of the GoF phenotypes could affect risk of a laboratory infection. Viruses that grow to a high titer could increase the dose received by a victim via an aerosol or fomite-based exposure. Because the coronaviruses are already adapted to humans, and because there are no countermeasures in use for protecting against infections with this pathogen, other GoF phenotypes are not relevant for this pathogen. Table 6.6 shows the relative increase in the probability of a laboratory acquired infection predicted if modified strains of the coronaviruses are created. Enhancing the growth of the coronaviruses to achieve titers of 1E9 or 1E10/ml can significantly increase the risk that a laboratory acquired infection would occur because the exposures that drive risk are normally very low. Under these circumstances, contamination of the hands beings to significantly drive risk, growing to cause about 20% of all laboratory infections for strains that grow to 1E10/ml (not shown). That being said, SARS- and MERS-CoV already grow to a titer of 1E8/ml, and increasing this titer may not be desirable or scientifically achievable.

Table 6.6 Increase in the Probability of a Laboratory Acquired Infection Associated with GoF Phenotypes in the Coronaviruses

Phenotype	Increase in Probability of a LAI
Evasion of vaccines	N/A
Antiviral resistance	N/A
Growth to 1E9/ml	+260% (SARS-CoV), +160% MERS-CoV
Growth to 1E10/ml	+860 (SARS-CoV), +550% (MERS-CoV)
Adaptation to humans	N/A
**N/A marks a phenotype not applicable to the coronaviruses*	

6.4.4.5 Effect of various research conditions on risk on probability of loss of containment

6.4.4.5.1 Effect of changing the biosafety level when working with GoF pathogens

This section describes how changing the biosafety level of the laboratory in which GoF pathogens are manipulated changes risk. All GoF pathogens except for seasonal influenza are manipulated at BSL-3 containment at least. Increasing the containment level of seasonal influenza decreases the probability of a laboratory acquired infection by three-fold, which, notably, would partially compensate for the increases in risk caused by the riskiest GoF phenotypes. For all but avian influenza, the increase or decrease in risk is caused by the addition or elimination of personal respiratory protection (such as PAPRs). For avian influenza, fewer mistakes need to be committed to release infected solid waste at BSL-2 than BSL-3 leading to an increase in the frequency of infections of wild birds.

Table 6.7. Change in the Probability of a Laboratory Acquired Infection (LAI) for Changes in the Containment Level Required for Manipulating the GoF Pathogens

Pathogen	Change in BSL	Change in Probability of an LAI
Seasonal influenza	Increase from BSL-2 to BSL-3	3-fold decrease
Pandemic influenza	Decrease from BSL-3 to BSL-2	3.5-fold increase
Avian influenza	Decrease from BSL-3 to BSL-2	110-fold increase
SARS-CoV	Decrease from BSL-3 to BSL-2	Less than 2-fold increase
MERS-CoV	Decrease from BSL-3 to BSL-2	Less than 2-fold increase

In contrast, if any of the other GoF pathogens were manipulated under BSL-2 conditions instead of BSL-3, the probability of a laboratory acquired infection would, unsurprisingly, increase, although this increase is small for the coronaviruses. This analysis suggests that work on influenza viruses in parts of the world with less stringent biosafety standards than the US could be expected to have up to an order of magnitude more accidents resulting in an infection.

6.4.4.5.2 Factors That Influence the Probability of Accidents with Seasonal Influenza Virus

To understand which laboratory features and practices influence the probability of a laboratory acquired infection with the risk of causing an outbreak, a sensitivity analysis was performed in which the values of any parameter were set to the lowest or highest level while all other parameter values were allowed to vary as normal. The results of this sensitivity analysis for seasonal influenza at BSL-2 are shown in the one-sided tornado plot in Figure 6.20 wherein the width of the boxes shows the increase in the probability of an infection if the parameter is set from its value that minimizes the probability to the value that maximizes it.

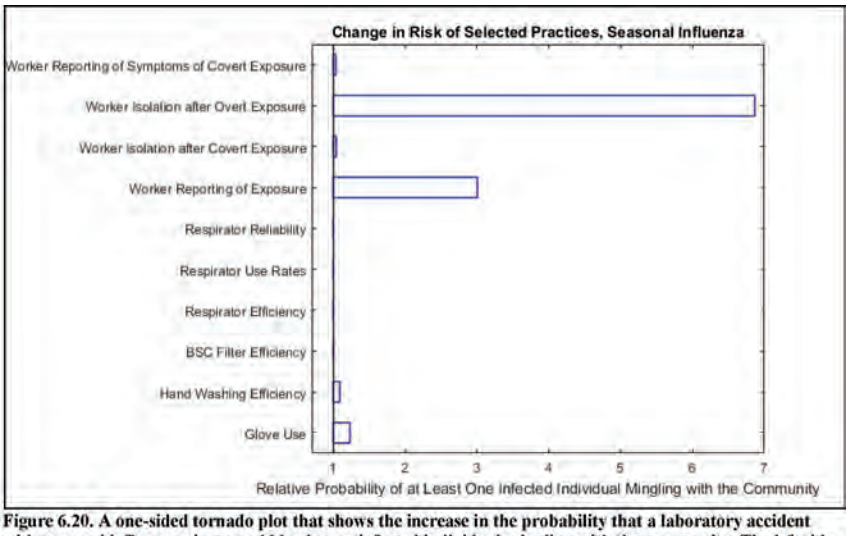

Figure 6.20. A one-sided tornado plot that shows the increase in the probability that a laboratory accident with seasonal influenza virus would lead to an infected individual mingling with the community. The left side of each box (set to one) represents that value of that parameter that minimizes this probability, whereas the right side is the value that maximizes this probability.

The most influential features that influence the risk of an infection occurring and that worker posing a risk to the community is the behavior of that worker. Maximizing the probability that a worker will not properly report a high-risk exposure can increase the probability of a dangerous infection by a three-fold. Similarly, maximizing the chance that a worker violates isolation protocols after an overt exposure can increase risk by seven-fold. For this reason, extensive training on the benefit of reporting, health monitoring and isolation could increase compliance and greatly reduce risk. No other parameter is very influential (partially because respirators are not worn in BSL-2).

6.4.4.5.3 Factors That Influence the Probability of Accidents with Pandemic Influenza Virus

The results of the sensitivity analysis for pandemic influenza at BSL-3 are shown in the one-sided tornado plot in Figure 6.21. The width of the boxes shows the increase in the probability of an infection if the parameter is set from its value that minimizes the probability to the value that maximizes it.

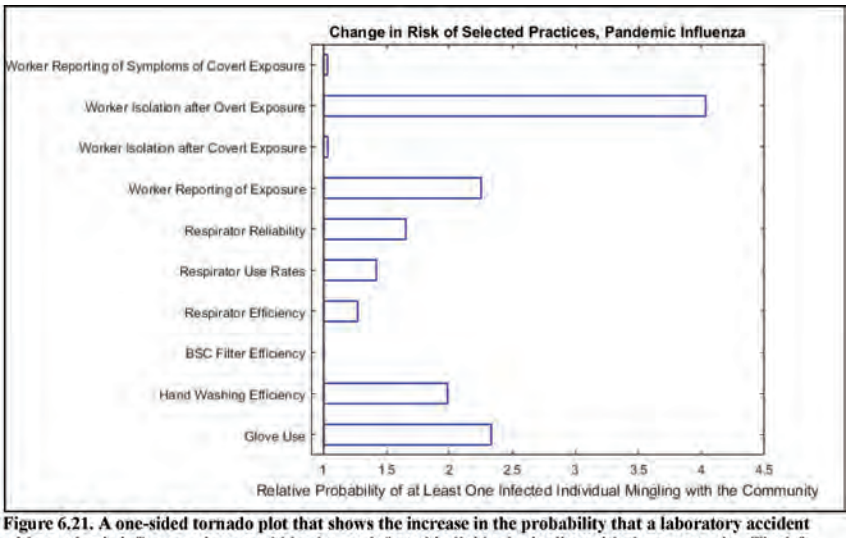

Figure 6.21. A one-sided tornado plot that shows the increase in the probability that a laboratory accident with pandemic influenza virus would lead to an infected individual mingling with the community. The left side of each box (set to one) represents that value of that parameter that minimizes this probability, whereas the right side is the value that maximizes this probability.

The most important practice of reducing the probability of a dangerous infection with pandemic influenza is the isolation of possibly infected workers (poor isolation practices increase the risk of an infection by four-fold). Similarly, poor reporting of exposure can more than double the probability of a double infection. Failure to double glove can more than double the probability of an infection, whereas poorly functioning or fitted respirators can nearly double this probability.

6.4.4.5.4 Factors That Influence the Probability of Accidents with Avian Influenza Virus

The results of the sensitivity analysis for avian influenza at BSL-3 are shown in the one-sided tornado plot in Figure 6.22 wherein the width of the boxes shows the increase in the probability of an infection if the parameter is set from its value that minimizes the probability to the value that maximizes it. No feature or practice in the assessment conducted influences the probability of a dangerous infection by more than 1.5-fold, which makes sense because most of the risk is driven by errors in solid waste processing.

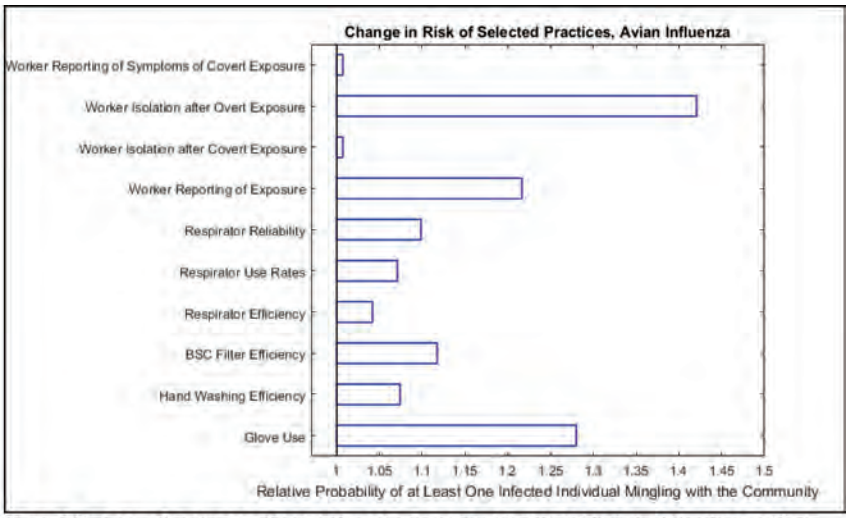

Figure 6.22. A one-sided tornado plot that shows the increase in the probability that a laboratory accident with avian influenza virus would lead to an infected individual mingling with the community. The left side of each box (set to one) represents that value of that parameter that minimizes this probability, whereas the right side is the value that maximizes this probability.

6.4.4.5.5 Factors That Influence the Probability of Accidents with Coronaviruses

The results of the sensitivity analysis for the coronaviruses at BSL-3 are shown in the one-sided tornado plot in Figure 6.23 wherein the width of the boxes shows the increase in the probability of an infection if the parameter is set from its value that minimizes the probability to the value that maximizes it.

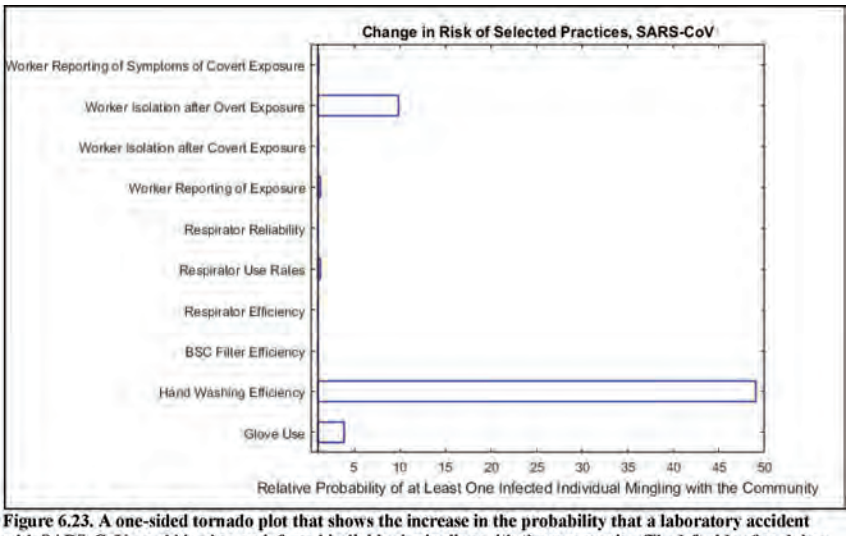

Figure 6.23. A one-sided tornado plot that shows the increase in the probability that a laboratory accident with SARS-CoV would lead to an infected individual mingling with the community. The left side of each box (set to one) represents that value of that parameter that minimizes this probability, whereas the right side is the value that maximizes this probability.

Three practices have a significant influence on the probability that an infection occurs and the worker mingles with the community. Firstly, failure to double glove can increase the probability by up to four-fold. From the same exposure pathways, poor hand washing can increase the probability by nearly 50-fold. These findings demonstrate that worker education and training on proper techniques for reducing hand contamination may significantly reduce risk of working with the coronaviruses. Also, poor adherence to isolation protocols can increase the probability that an infected worker mingles with the population by ten-fold. Once again, training on the importance of health monitoring and isolation could greatly reduce risk.

The results for MERS-CoV follow the same overall trends, and are shown in Figure 6.24, below.

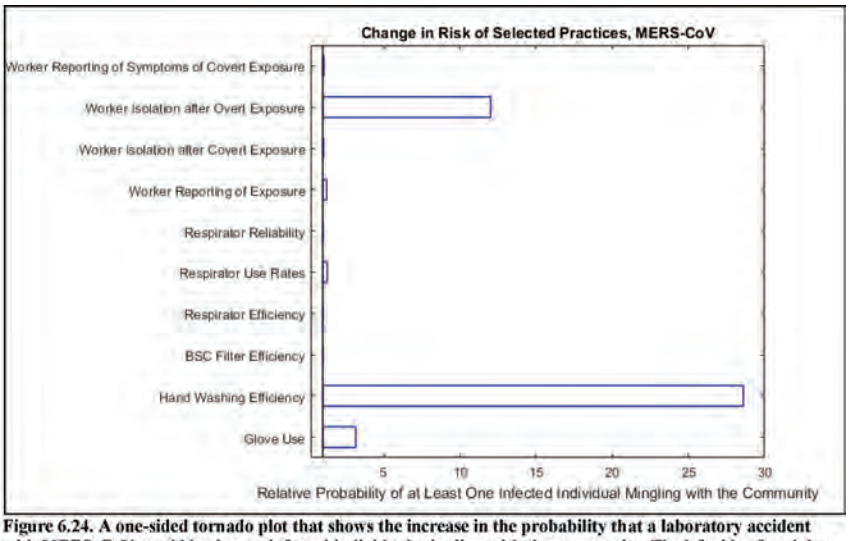

Figure 6.24. A one-sided tornado plot that shows the increase in the probability that a laboratory accident with MERS-CoV would lead to an infected individual mingling with the community. The left side of each box (set to one) represents that value of that parameter that minimizes this probability, whereas the right side is the value that maximizes this probability.

6.4.4.5.6 Importance of Laboratory Worker Training

By far, the most critical driver of the probability of a dangerous infection is the behavior of workers themselves. As discussed above, the probability that a worker reports a high risk exposure or adheres to isolation protocols can significantly influence the probability that an infected worker would mingle with the population. However, the probability that a worker would carelessly or forgetfully cause the incident in the laboratory is the most influential factor on risk. Figure 6.25 shows the relative influence of parameters influencing human error rates in the laboratory against all other parameters investigated. In this instance, all nodes in the fault trees that were based on the probability of a human error occurring had their failure probabilities (i.e., the probability a mistake is committed) simultaneously set to their maximum or minimum values. Only human errors that occur within the laboratory leading to an accident were considered; the probabilities of human errors occurring after an incident occurs, such as failures to report incidents or remain in isolation, were unchanged in this analysis. From this figure, human error rates can influence the probability of an infection by more than 100-fold (whereas the next most influential parameter for seasonal influenza changes this probability by nearly tenfold). Across all pathogens studied, human error rates in the laboratory this type of parameter influence the probability of a dangerous infection from 100-1,000-fold (data not shown).

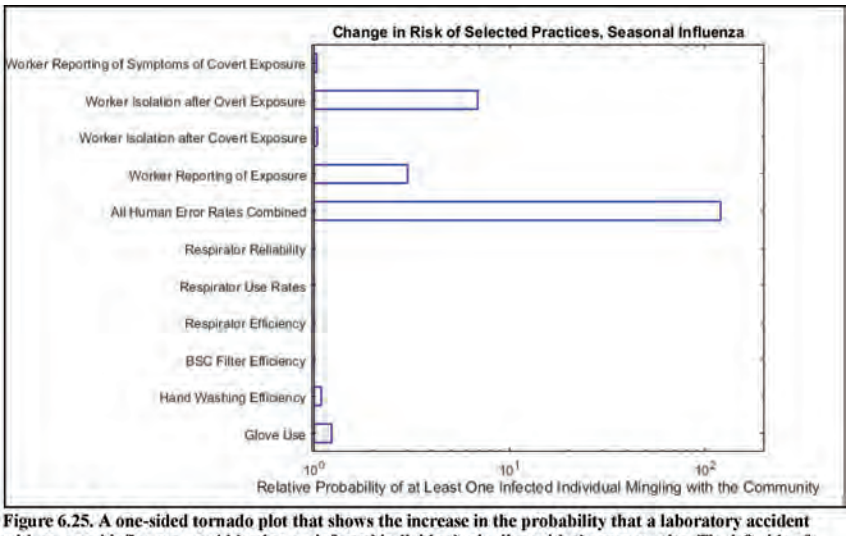

Figure 6.25. A one-sided tornado plot that shows the increase in the probability that a laboratory accident with seasonal influenza would lead to an infected individual mingling with the community. The left side of each box (set to one) represents that value of that parameter that minimizes this probability, whereas the right side is the value that maximizes this probability. The x-axis is on a log scale.

This analysis reflects both aleatoric and epistemic uncertainty. That is, data are lacking on how often humans will make mistakes of a variety of kinds in a biological laboratory (epistemic uncertainty). However, even if relevant observational data were available to inform these human error rates, significant aleatoric uncertainty would remain. That is, laboratory workers are humans and some humans are more prone than others to errors due to carelessness, unfamiliarity with protocols, distraction, or stress. Many who have experience working in a microbiology laboratory could identify co-workers with whom no one would share reagents due to the perception that the co-worker would contaminate or otherwise compromise the reagent. Aleatoric uncertainty will always exist because at any given time, it is unknown which type of person will be working in the laboratory (and what stresses they will be under). This analysis suggests that efforts to reduce stressors on workers could significantly improve laboratory safety. Also, measures to identify and re-train workers that are prone to carelessness or forgetfulness may have similar benefits. Moreover, as described by the laboratory safety stakeholders we interviewed, efforts to "train-in" to a BSL-3 laboratory by first demonstrating competence and mastery of protocols in a BSL-2 laboratory could significantly improve safety. Lastly, some stakeholders mentioned that dedicated professionals handle some sensitive laboratory protocols, such as the operation of autoclaves, to reduce the probability of the release of contaminated materials. Such practices would also significantly improve safety.

6.5 Consequences of an Outbreak Caused by an Avian Influenza Strain That Is Not Transmissible in Mammals

As discussed in the methods, we are unable to adequately model the human health consequences of an outbreak of an influenza virus that is not transmissible amongst people but is maintained in birds. Our simple models, based on the characteristics of past avian influenza outbreaks, suggest that an average of

100 people would die and 1,000 people would be clinically ill from contact with infected wild birds or poultry.

Most GoF phenotypes would not affect risk (clearly, if the strain were made transmissible in mammals, risk could change greatly as explored in Section 6.7 below). Enhanced growth in culture would not affect the outbreak unless this trait was related to pathogenicity or infectiousness. Ability to overcome immunity would not increase risk because most humans have no prior immunity from exposure to avian strains and novel vaccines are not stockpiled in quantity for an outbreak of influenza that is not human transmissible. Resistance to antivirals is of minimal risk because some wild type strains of avian influenza are already resistant and antivirals at most would reduce the number of deaths by half (and the role of antivirals in preventing onward transmission is moot).

No prediction was able to be made on how adaptation to a mammalian host, which could reduce the median infectious dose, affects risk. The infectious dose of any given strain of avian influenza in humans is unknown as is the dose to which past victims had been exposed to. It is possible that upon exposure to an infected bird, a human receives either a large dose or no dose at all (if, for example, infection is generally caused by inoculation with a globule of infected feces that could contain billions of active virus particles). In this case, a reduction of the median infectious dose would minimally affect risk. Conversely, many people could be exposed to very low doses and not become infected; if the infectious dose decreased perhaps all these people would develop illness.

In a simple way, the effect of an increased case fatality rate on risk can be made. Figure 6.26 shows the human deaths predicted to occur from an outbreak of wild type avian influenza, an outbreak caused by a strain that causes an illness with half the rate of survival of wild type avian influenza, and an outbreak that causes an illness caused by a strain with quarter the rate of survival of wild type avian influenza. Decreases in rates of survival must be modeled instead of increases in death rates because the fatality rate could be as high as 50% in some wild type strains. Outbreaks of wild type avian influenza are predicted to cause about 100 deaths, and very few outbreaks would cause up to 500 deaths. If a strain were modified to decrease the survival rate in victims by half, the outbreaks cause about 300 deaths on average, but up to 700 deaths in rare cases. If a strain were modified to decrease the survival rate in victims by a quarter, the outbreaks cause about 500 deaths on average, but up to 900 deaths in rare cases. This analysis presumes that the most pathogenic strains of avian influenza have an inflated case fatality rate due to the under-reporting of mild cases. If the case fatality rate of the most pathogenic strains of avian influenza is truly 50% then increasing this trait would not make the strain much more dangerous.

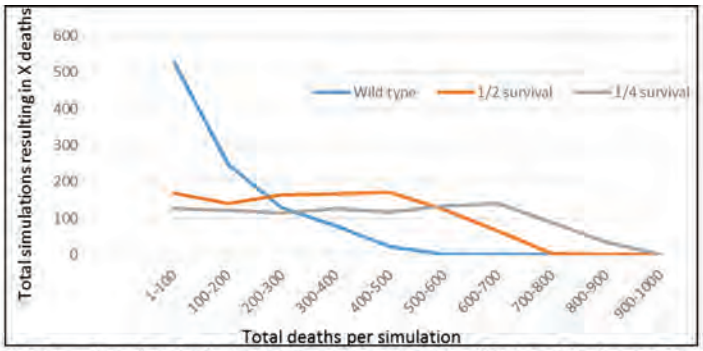

Figure 6.26. The number of outbreak simulations (out of 1,000 per condition) resulting in a number of deaths for wild type avian influenza and strains modified to be more pathogenic. Outbreaks of wild type avian influenza are in blue, outbreaks of a strain that causes disease with half the survival rate of wild type avian influenza are in orange, and outbreaks of a strain that causes disease with quarter the survival rate of wild type avian influenza are in grey.

That being said, the state of modeling of avian influenza outbreaks in human populations is very rudimentary, so confident predictions of the risk of modified avian influenza strains in human populations is currently impossible. Additional data on the risk factors that lead to human infection, the life cycle of disease in its various avian hosts and factors that relate the biology of the virus to the pathology in the various hosts is needed to improve modeling of this infectious disease.

6.6 Risk of an Outbreak Escaping Local Control of Pathogens That Are Transmissible in Mammals

After an outbreak is initiated, the GoF phenotype of enhanced growth characteristics in culture or eggs no longer has any influence on risk. If this phenotype also increases transmissibility in humans, then the models capture changes in risk through those parameters. Pathogenicity is indirectly captured in the probability that an outbreak escapes local control. That is, the strength of public health control measures and social distancing exerts a critical influence on the probability that an outbreak escapes local control, which is assumed to be stronger when the outbreak is causing significant mortality than when the outbreak resembles a typical influenza season. Pathogenicity directly influences consequences in terms of the number of deaths that occur should an outbreak not escape local control (if the outbreak escapes, then the consequences will be dominated by the global deaths summed across all regions, not the deaths in one community). Ability to overcome immunity induced by vaccination is not relevant because a matched vaccine will not be available in quantity in time to respond to the initial outbreak.

Antivirals have never been dispensed to address a nascent outbreak of influenza, and public health authorities interviewed have no concrete plans for the use of antivirals in an outbreak arising from a local laboratory. For this reason, we do not know if, in the case of a laboratory-associated outbreak, antivirals would be mass dispensed to the entire outbreak area, if they would be distributed to all contacts of an infected person, or if they would just be given to the infected individuals. Moreover, some strains of influenza are naturally resistant to antivirals, and we do not know which strain would be involved in an outbreak. For these reasons, antivirals were not included in the branching process model. Because data exists on how antivirals are used in the context of an ongoing global pandemic of influenza, antivirals are included in the global influenza models described in Section 6.11, below. Similarly, antivirals can be

given upon high-risk exposures in the laboratory to prevent the onset of illness or reduce transmissibility if an infection occurs, as described in Section 6.4.

All of the figures shown assume that just one person is initially infected. These events dominate risk because they are much more likely to occur and have similar consequences to events that initially infect multiple people. As discussed in Figure 6.27 below, increasing the number of initially infected at most increases the probability of a global pandemic by ten-fold. However, events that lead to a single initial infection are more than 100-fold more likely to occur.

Even if an infected person mingles with the local population, secondary infections in the population are not guaranteed. In fact, for some poorly transmissible pathogens (or the coronaviruses that have a high variance in transmissibility), in most cases no secondary cases are caused just by chance. Figure 6.27 shows the relationship between transmissibility and the percent of outbreaks that create at least one secondary infection for the influenza viruses and the coronaviruses. When a single person infected with seasonal influenza mingles with the population, another person is infected just half the time (and this probability increases modestly as R_0 increases). In contrast, when a single person infected with a SARS-like disease mingles with the population, at least one secondary case is caused only 30% of the time, which is expected given the high variance of the transmissibility of that disease. If two infected people mingle with the population, the chances that at least one secondary infection is caused increases. Perhaps most importantly, as transmissibility increases dramatically, the probability of at least one secondary infection increases only modestly, by less 15% for an increase in R_0 of one (except for very low values of R_0). The chance that an infected person does not cause any secondary infections is integrated into the analysis of outbreaks escaping local control described below.

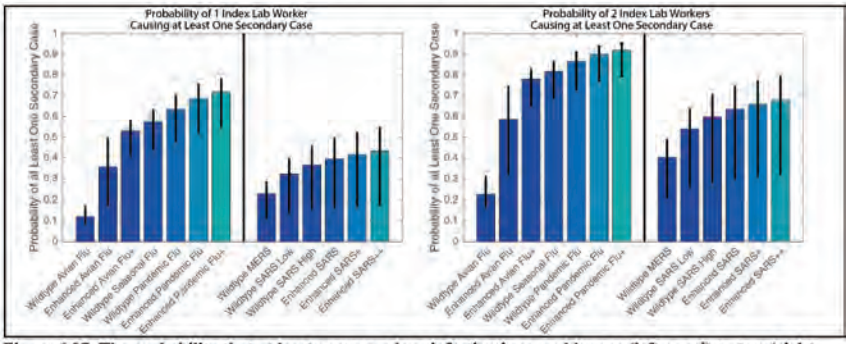

Figure 6.27. The probability that at least one secondary infection is caused by one (left panel) or two (right panel) infected people mingling with the population for various wild type and enhanced viruses. The R_0s used in this figure are 0.1-0.2 for wild type avian influenza, 0.2-1.0 for enhanced avian influenza, 1.0-1.2 for enhanced avian influenza+, 1.2-1.4 for wild type seasonal influenza (this value also captures 1918 H1N1 pandemic influenza in a modern population), 1.4-1.9 for wild type pandemic influenza (specifically strains for which our population has little residual immunity), 1.9-2.2 for enhanced pandemic influenza, 2.2-2.5 for enhanced pandemic influenza+, 0.4-0.6 for wild type MERS-CoV, 0.8-1.2 for wild type SARS-CoV low, 1.2-1.6 for wild type SARS-CoV high, 1.6-1.9 enhanced SARS-CoV, 1.9-2.2 enhanced SARS-CoV+, 2.2-2.5 for enhanced SARS-CoV++. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented). In this figure, "pandemic flu" is used to describe those pandemic influenza strains against which the population has little immunological memory (e.g., 1957 H2N2 pdm) whereas 1918 H1N1 pdm is as transmissible as a seasonal influenza strain due to recent exposure of the population to the 2009 H1N1 pdm and more recent

seasonal strains (See Supplemental Information - Protection against Infection with 1918 H1N1 Pandemic Strain).

6.6.1 Effect of Enhanced Transmissibility in Mammals on Risk of an Outbreak Escaping Local Control

Transmissibility has a significant influence on the chance that an outbreak would escape local control for all GoF pathogens.

6.6.1.1 Seasonal Influenza

If a single person is initially infected by a loss of containment event with a seasonal influenza strain that has not circulated recently and the infected person mingles with the general population, stochastic forces, and control measures still cause the outbreak to extinguish the vast majority of the time. The tornado plot in Figure 6.28 illustrates how a variety of parameters influence the probability that an outbreak would escape local containment (the wider the box, the more influence that parameter value has on the outbreak escaping local control). This figure shows that an outbreak caused by a single infection with wild type seasonal influenza virus has a 20% chance of escaping local control. Of wild type strains, those with the highest R_0 values (1.4) have up to a 30% chance of escaping local control. If transmissibility were increased even further (to 2.2), the probability of an outbreak escaping local control could more than double to 60%.

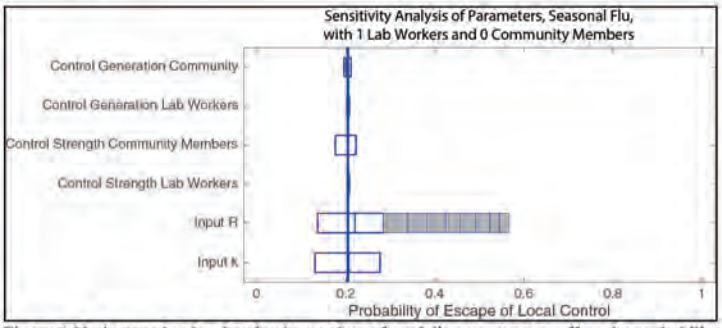

Figure 6.28. A tornado plot showing how values of modeling parameters affect the probability that an outbreak of seasonal influenza would escape local control if a single person were initially infected (shown on the Y-axis). Open boxes represent the range of probabilities that an outbreak would escape local control for all parameter values sampled for the wild type pathogen whereas grey boxes represent possible enhancements in a GoF strain. The vertical line shows the median result across all parameter values for an outbreak caused by a wild type strain.

Although the probability of an outbreak escaping local control is sensitive to the transmissibility of the strain that causes the outbreak, this increase poses a risk only if the creation of a strain with such properties is feasible. Figure 6.29 shows the relationship between the transmissibility of a seasonal influenza strain and the probability that a resulting outbreak would escape local control. These data show that modifying a wild type seasonal influenza strain associated with an average R_0 value (1.3) so that it has the transmissibility associated with an average pandemic influenza strain (1.7) doubles the probability that an outbreak would escape local control. Also of note, the least transmissible wild type strains (R_0 of

1.2) are roughly two-to-three-fold less likely to cause an outbreak that escapes local control as the most transmissible wild type strains (R_0 of 1.4).

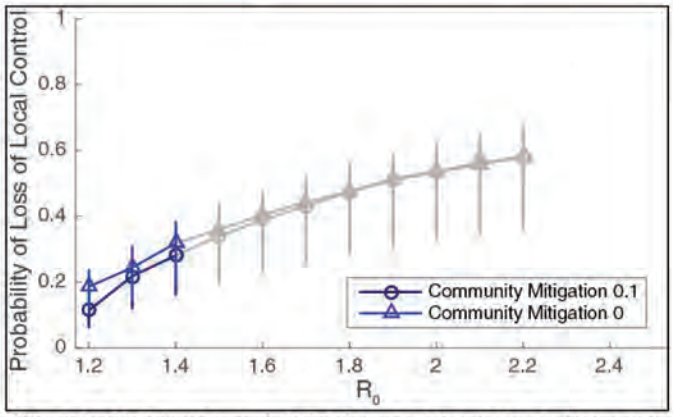

Figure 6.29. The relationship between transmissibility of seasonal influenza virus (as measured by the R_0 of the resulting outbreak) and the probability that an outbreak escapes local control. Grey represents various manipulations to increase the transmissibility of the virus beyond estimates for wild type strains. The colors correspond to those represented in the tornado plot in Figure 6.28. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented). The error bars reflect the effect of an uncertain k value (the variance in transmissibility of the disease among those infected) on the probability that an outbreak escapes local control. For this reason, for any particular k value, the relative increase in the probability that an outbreak escapes local should mirror the shape of the line given for the median result.

6.6.1.2 Pandemic Influenza

If a single person is initially infected by a loss of containment event with a pandemic influenza strain and that infected person mingles with the general population, stochastic forces, and control measures still cause the outbreak to extinguish the majority of the time. Figure 6.30 shows that an outbreak caused by a single infection with wild type pandemic influenza virus has a 20% chance of escaping local control (because the transmissibility of 1918 H1N1 pdm is less than that of new seasonal strains due to recent exposure to 2009 H1N1 pdm, see Supplemental Information - Protection against Infection with 1918 H1N1 Pandemic Strain). However, our population has little residual immunity against the H2 pandemic strains, so some wild type pandemic strains have up to a 30% chance of escaping local control (the rightmost portion of the open box). If transmissibility were increased even further (to 2.5), the probability of an outbreak escaping local control could more than double to 50%.

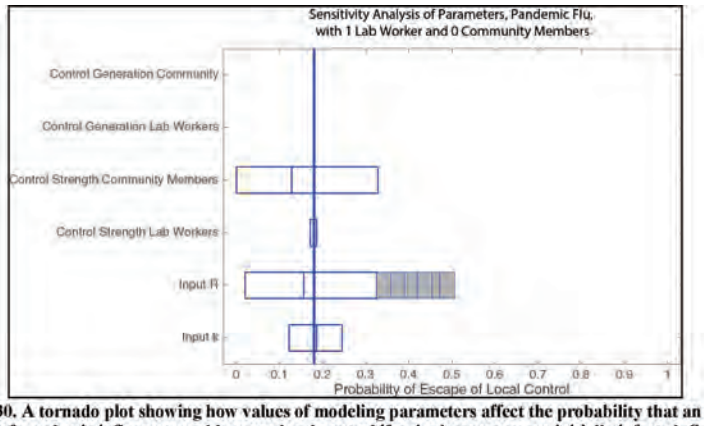

Figure 6.30. A tornado plot showing how values of modeling parameters affect the probability that an outbreak of pandemic influenza would escape local control if a single person were initially infected. Open boxes represent the range of probabilities that an outbreak would escape local control for all parameter values sampled for the wild type pathogen whereas grey boxes represent possible enhancements in a GoF strain. The vertical line shows the median result across all parameter values for an outbreak caused by a wild type strain.

Figure 6.31 shows the relationship between the transmissibility of a pandemic influenza strain and the probability that a resulting outbreak would escape local control. These data show that modifying a wild type pandemic influenza strain associated with an R_0 value of a strain against which little population immunity exists (like H2 strains, R_0 of 1.7) so that it has a transmissibility greater than any estimate for any influenza strain (2.4) merely increases the probability that outbreak escapes control by 50%. If, however, the local population can sustain robust social distancing throughout the nascent outbreak (for example, by reducing the number of human contacts they have by half, shown as a community mitigation of 0.5 in the figure below), these extreme R_0 values would be *required* for the outbreak to have any chance of escaping local control. This finding is intuitively obvious because halving all contacts would reduce an R_0 value of two to an R_0 of one, which is required for the outbreak to be self-sustaining. It should be noted, however, that no experiment performed to date has increased the transmissibility of an influenza strain more than the most highly transmissible strains, and it is unknown if this result is even feasible. In contrast, increasing the transmissibility of a poorly transmissible strain (like 1918 H1N1 pdm, which, due to recent population exposure to antigenically similar H1N1 strains, has a R0 closer to 1.2), can more than double the probability of an outbreak even if little community mitigation is assumed. Increasing the transmissibility to that of other pandemic strains (by, for example, changing its antigenic properties) would double the probability of escape, and increasing the transmissibility further could triple the chance of escape.

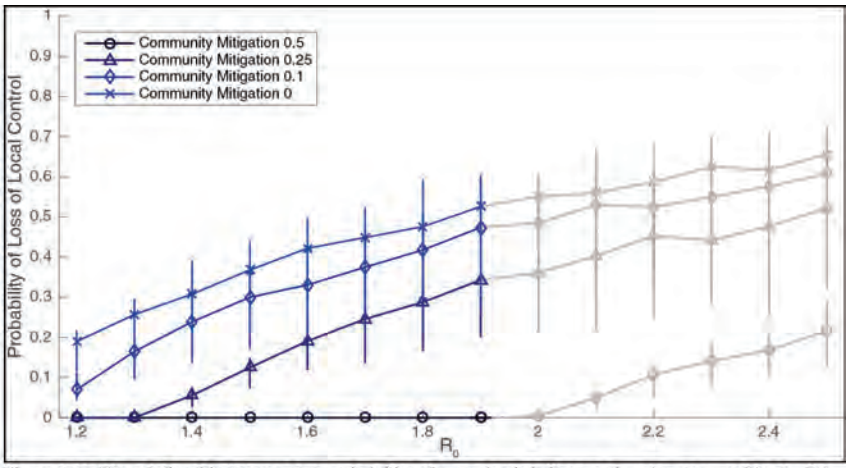

Figure 6.31. The relationship between transmissibility of a pandemic influenza virus (as measured by the R0 of the resulting outbreak) and the probability that an outbreak escapes local control. Grey indicates various manipulations to increase the transmissibility of the virus beyond estimates for wild type strains. The colors correspond to those represented in the tornado plot in Figure 6.30. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented). The error bars reflect the effect of an uncertain k value (the variance in transmissibility of the disease among those infected) on the probability that an outbreak escapes local control. For this reason, for any particular k value, the relative increase in the probability that an outbreak escapes local should mirror the shape of the line given for the median result.

6.6.1.3 Avian Influenza

Wild type avian influenza virus is insufficiently transmissible in mammals to cause an outbreak that escapes local control. Figure 6.32 shows how transmissible in people a modified strain of avian influenza would have to be to escape local control should one laboratorian be initially infected and mingle with the general population. Unless robust social distancing measures can be implemented throughout the outbreak (community mitigation 0.5 in the figure below), increasing the transmissibility of an avian influenza strain in humans to that of seasonal influenza would lead to a local outbreak with about a 10-20% chance of escaping local control. Given that the wild type strain has no chance of creating an outbreak that escapes local control (or even one that is made modestly more transmissible) this increase is extremely significant.

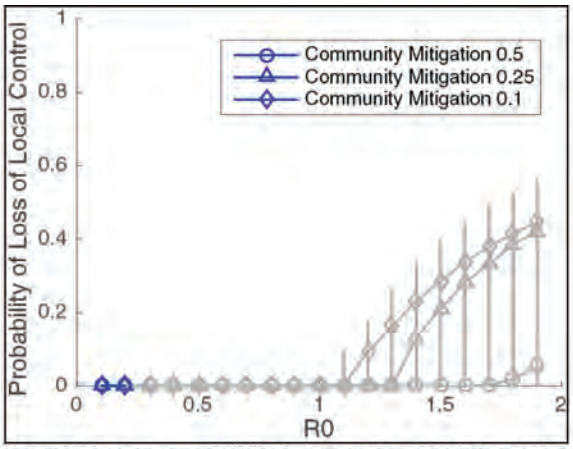

Figure 6.32. The relationship between transmissibility in humans of an avian influenza virus (as measured by the R0 of the resulting outbreak) and the probability that an outbreak escapes local control. Grey points indicate various manipulations to increase the transmissibility of the virus beyond estimates for wild type strains. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented). The error bars reflect the effect of an uncertain k value (the variance in transmissibility of the disease among those infected) on the probability that an outbreak escapes local control. For this reason, for any particular k value, the relative increase in the probability that an outbreak escapes local should mirror the shape of the line given for the median result.

6.6.1.4 Coronaviruses

If a single person is initially infected by a loss of containment event with SARS-CoV and that person mingles with the general population, stochastic forces and control measures still cause the outbreak to extinguish. Figure 6.33 shows that an outbreak caused by a single infection with wild type SARS-CoV has nearly no chance of escaping local control. The historical outbreaks of coronaviruses reinforce this finding because although these outbreaks lead to infections in several locations, they did not initiate a global pandemic because local control of the outbreak was successful in every outbreak location. As described in the Supplemental Information, most researchers consider the highest estimates for the value of R_0 to be 1.6 for outbreaks caused by wild type SARS-CoV. This value is useful for a biosafety analysis because it automatically considers the spontaneous, uncoordinated control measures that would occur until the outbreak is identified. Some researchers have estimated the R_0 to be as great as 3.0 if only the absolute earliest stage of the outbreak is considered, the strictest meaning of the term R_0.[362, 363] For our analysis, we have restricted "wild-type" SARS-CoV to R_0 values of 1.6 or less, but we also describe how a higher baseline R_0 value affects risk.

[362] Lipsitch, M., et al., Transmission dynamics and control of severe acute respiratory syndrome. Science, 2003. 300(5627): p. 1966-70.

[363] Wallinga, J. and P. Teunis, Different epidemic curves for severe acute respiratory syndrome reveal similar impacts of control measures. Am J Epidemiol, 2004. 160(6): p. 509-16.

As figure 6.33 shows, wild type SARS-CoV have nearly no chance of escaping local control. If we assume that community mitigation is poor, some outbreaks have up to a 10% chance of escaping local control.

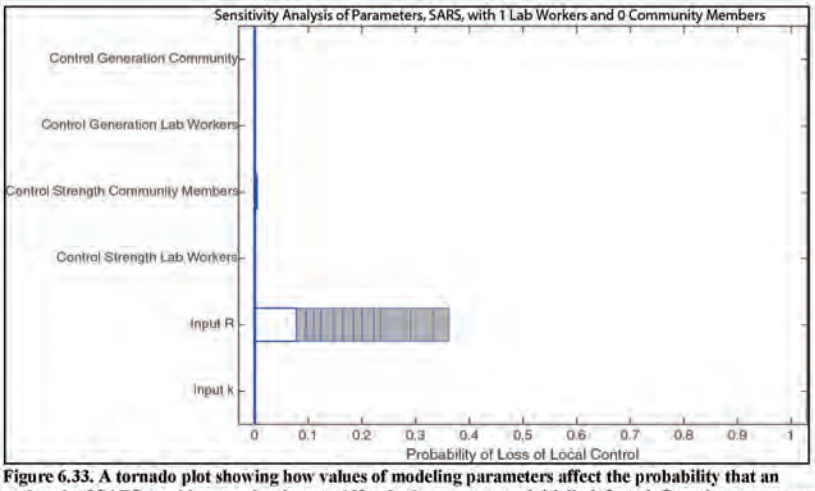

Figure 6.33. A tornado plot showing how values of modeling parameters affect the probability that an outbreak of SARS would escape local control if a single person were initially infected. Open boxes represent the range of probabilities that an outbreak would escape local control for all parameter values sampled for the wild type pathogen (assuming the R_0 value does not exceed 1.6) whereas grey boxes represent possible enhancements in a GoF strain (or greater values for the R_0 for the wild type). The vertical line shows the median result across all parameter values for an outbreak caused by a wild type strain.

Wild type MERS-CoV is not transmissible enough to cause an outbreak to escape local control. Should a MERS-CoV be modified to be as transmissible as SARS-CoV, then its probability of escaping local control would be similar.

As transmissibility of SARS-CoV increases, the probability that an outbreak escapes local control increases. The relationship between transmissibility and probability of an outbreak escaping is shown in Figure 6.34. As mentioned above, wild-type SARS-CoV has only a 10% chance of escaping local control if poor community control is assumed. If transmissibility were increased (to an R_0 of 3), the probability of an outbreak escaping local control could increase significantly to 30%. Increasing the transmissibility beyond 3.0 to 4.0 has a modest effect on the probability of escape (increasing from 30% to 38%, or roughly by 30%). In short, if the R_0 value of wild-type SARS-CoV is low (R_0 of 1.6 or less) then increasing this value can significantly increase risk. If the R_0 value of wild-type SARS-CoV is already great (R_0 of 3.0) then further increases do little to increase risk. The relationship for MERS-CoV is similar to that shown in Figure 6.34 except that GoF experiments that increase transmissibility must be conducted for the pathogen to have any chance of creating an outbreak that escapes local control.

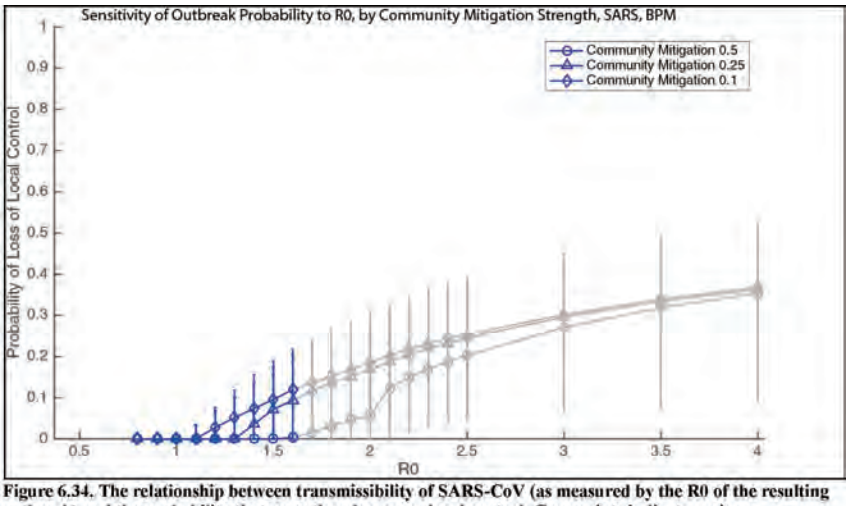

Figure 6.34. The relationship between transmissibility of SARS-CoV (as measured by the R0 of the resulting outbreak) and the probability that an outbreak escapes local control. Grey points indicate various manipulations to increase the transmissibility of SARS-CoV in humans beyond the highest estimates for the first few generations of infections caused by the virus (R_0=1.6). We here show the probability of escape of a SARS-CoV with an R_0 of 3.0 as well. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.6.2 Effect of Enhanced Pathogenicity on Risk of an Outbreak Escaping Local Control

6.6.2.1 Pandemic/Seasonal Influenza

All influenza outbreaks that extinguish do so when the outbreak is relatively small. For this reason, even the most highly pathogenic strains influenza would lead to only a handful of deaths (we predict that even a 1918-like strain would not result in, on average, even one fatality if the outbreak extinguished locally). If the outbreak escaped local control and spread throughout the world, vastly more deaths could occur, but these consequences are assessed in Section 6.11.

Interestingly, an outbreak associated with significant mortality may trigger more robust and prolonged social distancing, which would greatly decrease the chance that an outbreak would spread beyond local control. For this reason, an outbreak caused by a strain that is modified to be more deadly may actually reduce risk, although we cannot quantify how the public will react to a novel outbreak.

6.6.2.2 Avian Influenza

Wild type avian influenza strains are already associated with a high case-fatality rate and so increasing this rate would probably have little influence on the robustness of a public health response. Moreover, wild type avian influenza strains are insufficiently transmissible in humans to cause an outbreak that would escape local control.

6.6.2.3 Coronaviruses

Infections with wild type SARS- and MERS-CoV is already associated with a relatively high case fatality rate. Increasing this rate is likely to have little influence on the robustness of social distancing. Also, because the case fatality rate is already significant, increasing this rate has little influence on the number of deaths expected. For SARS and MERS outbreaks that start with one person and extinguish locally, we expect less than ten people to die even if the strain were modified to be more pathogenic.

6.6.3 Effect of Overcoming/Evading Natural/Residual/Innate Immunity on the Probability of an Outbreak Escaping Local Control

6.6.3.1 Pandemic/Seasonal Influenza

Innate/residual immunity in a population can significantly affect the kinetics of an outbreak of influenza because prior exposure to recently circulating strains of influenza affords protection against similar serotypes. The protective value of residual/innate immunity is already accounted for in the effective R_0, which is one reason why the R0 for seasonal influenza is significantly less than that of pandemic influenza strains that have not circulate recently (like H2 strains). Figure 6.35, below, shows the relation between reduction in innate or residual immunity and the probability that an outbreak would escape local control for given prior immunity values.

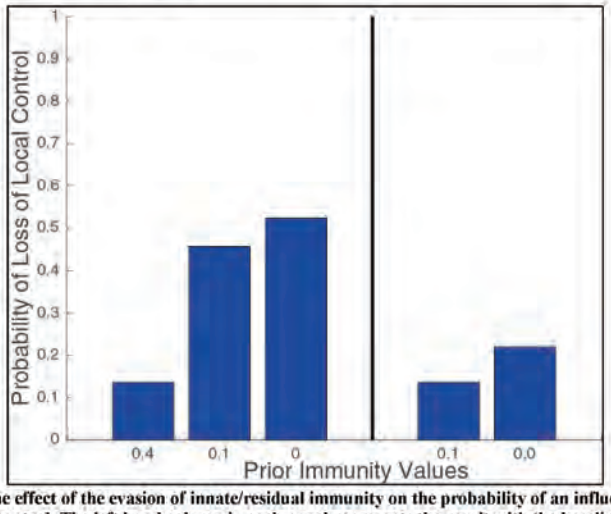

Figure 6.35. The effect of the evasion of innate/residual immunity on the probability of an influenza outbreak escaping local control. The left hand column in each panel represents the result with the baseline value of prior immunity. In the left-hand panel, the presumption is that 40% of the population is protected against infection with a wild type strain of influenza (either seasonal or pandemic, like 1918 H1N1 pdm). Under this condition the effect on the probability of escape if a strain (with the same R_0 value) were able to overcome most of this residual/innate immunity (so that only 10% of the population were immune) or overcome all immunity is shown. In the right-hand panel, the presumption is that 10% of the population has immunity to the wild type strain. Under this condition, the effect on the probability of escape is shown for strains that are modified to overcome all immunity.

This analysis demonstrates that the evasion of pre-existing immunity can significantly increase the probability of an outbreak of influenza escaping local control, by two-to-three-fold, if the population has a high level of residual immunity (as is likely for seasonal influenza since prior vaccination or illness provides some protection against new strains and 1918 H1N1 pdm influenza). Similar to R_0, this parameter influences the probability of an outbreak escaping by enabling the disease to spread more quickly (because each contact is more likely to result in an infection). Pre-existing immunity can protect a significant proportion of the population if the strain released is similar (or identical) to a strain of influenza that recently circulated, which is one reason why this parameter is highly influential. If the population exhibited relatively low levels of prior immunity, then evasion of prior immunity has little influence on consequences (increasing the probability of escape by less than a fifth).

6.6.3.2 Avian Influenza

Because very few humans have been previously exposed to avian subtypes of influenza and because wild type strains are poorly transmissible in people, residual immunity has essentially no bearing on the probability that an outbreak would escape local control.

6.6.3.3 Coronaviruses

Because very few humans have been previously exposed to SARS- or MERS-CoV, residual immunity has essentially no bearing on the probability that an outbreak would escape local control.

6.6.4 Effect of Loss of Containment Pathways on Risk of Loss of Local Control of an Outbreak

The nature of the incidents that could lead to a loss of containment event affect the probability of an outbreak escaping local control in three ways:

1. Incidents can be covert or overt and faster implementation of control measures is possible with overt incidents,
2. Incidents can initially infect a laboratory worker or member of the public, and
3. Incidents can infect a single person or multiple people

In this section we explore how the loss of containment pathway affects probability of an outbreak.

6.6.4.1 Overt Versus Covert Incidents

Some incidents are easy to recognize by the public health and laboratory safety communities as having a very high probability of causing infections outside the laboratory. In the biosecurity assessment, discussed in Chapter 7, the self-announcing events include mass shootings and bombings of the laboratory. In the biosafety assessment, the only event that poses a risk of loss of containment that falls into this category is the earthquake. If an earthquake strikes a laboratory such that obvious physical damage occurs that breaches the containment suites, the response community is likely to adopt measures assuming that the population is at risk of an infection and potential outbreak. Moreover, the community, fearful of the work done in the laboratory, are likely to significantly change their behaviors. Lastly, many laboratory buildings that house work on wild type influenza- or coronaviruses also house work on other human pathogens, so any work done on influenza- and coronaviruses may contribute only a portion of the overall risk of such an event.

If we assume that control measures can be immediately implemented but these control measures are no stronger than those implemented in a laboratory-based outbreak caused by other events, the probability than an outbreak escapes local control is decreased only modestly if at all (Figure 6.36).

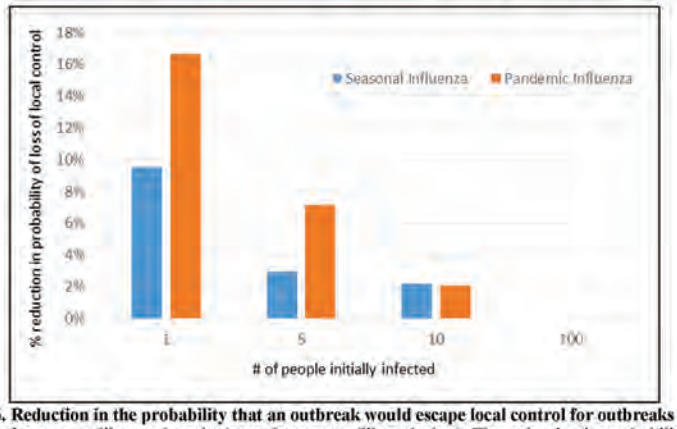

Figure 6.36. Reduction in the probability that an outbreak would escape local control for outbreaks caused by self-announcing events (like earthquakes) vs other events (like splashes). The reduction in probability is small and drops to zero for self-announcing events that initially infect large numbers of people.

If immediate and strong social distancing measures can be adopted (such that people halve the number of contacts they normally have) when an obvious breach in the laboratory is recognized, then no outbreak escapes local control. This result may be intuitively obvious because most outbreaks caused by a wild type influenza virus have an R_0 value less than two and this degree of control would drop the R_0 below one, which is required for the outbreak to be self-sustaining. We have no data to determine how people would behave after a large earthquake destroys a containment laboratory in the context of the chaos caused by the larger event. Perhaps a catastrophic earthquake would naturally reduce the contact between people in the community because school and work will be suspended. Alternatively, perhaps large number of people gathering in shelters would *increase* the contact between individuals and make outbreak control extremely difficult.

Due to the irreducible uncertainty and the minimal effect of the implementation of immediate control measures (which are assumed to be similar in strength to those implemented after a covert loss of containment event), the biosafety analysis assumes that an outbreak in the aftermath of an earthquake that destroys the laboratory has the same chance of coming under local control as any other outbreak. Similarly, in the biosecurity section, since the self-announcing events strike the laboratory with minimal consequences elsewhere (like a bombing or mass shooting), we presume that immediate control measures can be implemented to control the resulting outbreak although these have a minimal additional influence on the outbreak escaping local control.

6.6.4.2 Initial Infections of the Public Versus Initial Infections of Laboratory Workers

If a worker violates the protocol and mingles with the general population while sick, this person has the nearly the same probability of causing an outbreak that spreads beyond local control as an infected member of the public (not shown). The fact that a laboratory worker is trained to report early symptoms

of unusual illness, preemptively self-isolate (and potentially receive prophylactic antivirals) significantly reduces the probability that a worker will not mingle with the general population, as explained above.

6.6.4.3 Initial Numbers of People Infected

Depending on the loss of containment pathway, one, two, or more people could be infected by the event. The vast majority of loss of containment events lead to the infection of one laboratorian who contaminated her hands, failed to decontaminate them thoroughly, and then infected herself and no one else due to the contamination. However, some loss of containment events lead to multiple people infected either directly (via aerosols generated inside the laboratory) or indirectly (via a contaminated worker who happens to physically contact several people soon after leaving the laboratory). Figure 6.37 shows how the probability of an outbreak escaping local control depends on the initial number of people infected for seasonal influenza, pandemic influenza, and SARS. If one person is infected with influenza and mingles with the local population, the outbreak has a 20-30% chance of seeding a global pandemic. As more people are initially infected, the outbreak has a much greater chance of growing beyond local control. Even with 100 initially infected individuals, a SARS outbreak has a minimal chance of escaping local control (unless the R_0 for the pathogen is at the high end of all estimates). In addition, a SARS outbreak has a minimal chance of seeding a global pandemic due to the efficacy of control measures at preventing its spread (unless it is the R_0 for an outbreak in the US is at the high end of estimates of R_0s estimated for this pathogen).

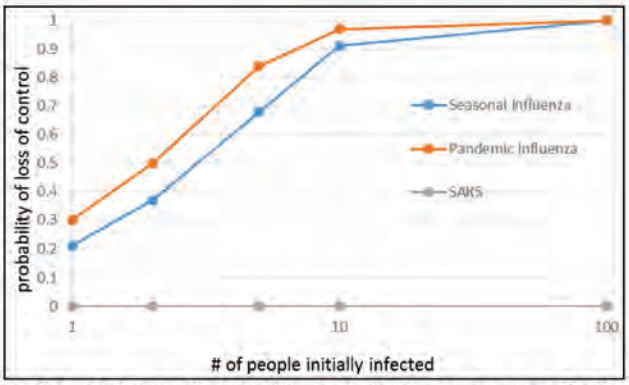

Figure 6.37. The relationship between the probability of an outbreak expanding beyond local control and the number of people initially infected by the loss of containment event. In this figure the median probability of an outbreak not extinguishing across all parameters for seasonal influenza, pandemic influenza and SARS are shown. The X-axis is on a log scale (the data points are for 1, 2, 5, 10 and 100 initial infections).

As explained above, the probability that a loss of containment event leads to the initial infection of one person is much more than ten times as likely as an event that initially infected multiple people. Since the probability of an outbreak escaping local control is not an order of magnitude greater for outbreaks in which more than one person is initially infected, incidents that infect exactly one person dominate the risk of a global outbreak. That is, because incidents that create exactly one index infection happen much more frequently than incidents that create multiple index infections, yet are still relatively likely to cause a global outbreak, these incidents are responsible for most of the global pandemics modeled.

6.7 Consequences of a Global Pandemic of Pathogens that Are Transmissible in Mammals

This section provides a description of the effect of GoF experiments on the consequences of a global pandemic. Because the relative risk of changing any phenotype depends upon the type of pathogen being modified (and its wild type traits), the phenotypes that have the most influence on risk for each pathogen are summarized first. In the sections that follow, a description is provided on exactly how risk changes as those phenotypes are altered.

After an outbreak is initiated, the GoF phenotype of enhanced growth characteristics in culture or eggs no longer has any influence on risk. If this phenotype also increases the transmissibility or pathogenicity in humans, then the models capture changes in risk through those parameters. Moreover, regardless of how the outbreak began, once it has spread globally the consequences of the global pandemic depend on the characteristics of the pathogen, not the means by which the outbreak was initiated.

6.7.1 Seasonal Influenza Virus

Even if a wild type strain of seasonal influenza sparked a global outbreak the consequences of this pandemic would eclipse those from all industrial accidents ever suffered. This section describes which GoF phenotypes would influence the consequences of a global outbreak of seasonal influenza strains. The GoF phenotypes relevant to an ongoing global outbreak of seasonal influenza are:

- The ability to overcome protective vaccination,
- The ability to overcome prior immunity (either natural or induced by previous vaccinations or infection by similar strains in the past),
- Resistance to antivirals,
- Transmissibility, and
- Pathogenicity (used here, case fatality rate)

The ability to evade diagnostics is of secondary importance to the effect of antivirals because diagnostics are used primarily to direct limiting stocks of these antivirals to only those truly infected. Few other effects of evading diagnostics exist at this stage of the outbreak because the agent causing the outbreak would already be identified by the time the outbreak has spread globally and mass vaccination (as soon as a protective vaccine were available) would occur instead of vaccination based on identified cases. Moreover, public health resources are insufficient for case isolation and quarantine when an outbreak has become global.

The GoF phenotypes of enhanced growth is irrelevant to an ongoing outbreak unless it influences transmissibility or pathogenicity (the risk of which are analyzed here). Adaptation to mammalian hosts is irrelevant for this pathogen because it is already adapted to infect and spread amongst humans.

To understand how various GoF phenotypes influence the consequence of a global outbreak, a sensitivity analysis was performed using the BARDA Interactive Influenza Model. In Figure 6.38 below, the value of any given parameter was set at its lowest level or its highest level to produce the mean numbers of deaths globally for those two values across model runs for all values of all other parameters. All parameters can be explored with this analysis simultaneously EXCEPT for prior/natural immunity in the

population because the estimated R_0 of a disease is calculated given natural levels of immunity (that is, the value of these two parameters are linked). We explore the ability of a pathogen to evade natural immunity separately.

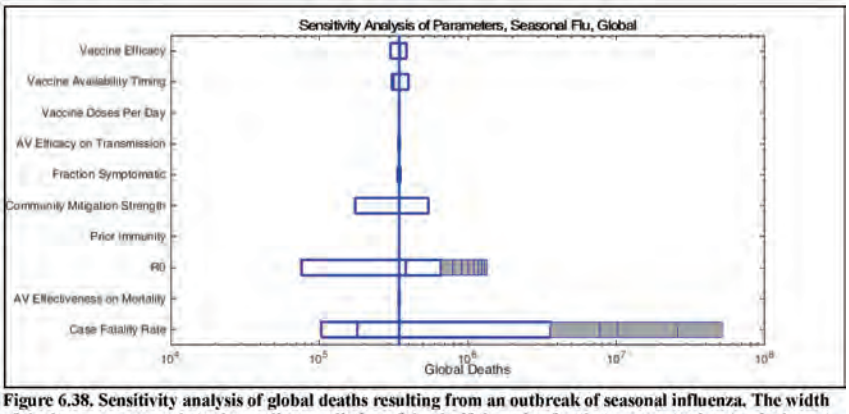

Figure 6.38. Sensitivity analysis of global deaths resulting from an outbreak of seasonal influenza. The width of the boxes corresponds to the median prediction of deaths if the value for that parameter is set to its lowest and highest level (and all other values are allowed to vary). Hollow boxes show the parameter value range for community control measures and wild type pathogens. Grey sections of the boxes show how increases in the transmissibility or pathogenicity beyond wild type levels affect consequences.

Firstly, this analysis demonstrates the great variability possible within the wild type strains that exist. The least deadly (non-attenuated) wild type strains are predicted to cause fifteen-fold fewer deaths globally than the most deadly wild type strains (from 100,000 to four million deaths). The least transmissible wild type strains (that have not circulated recently) are predicted to cause six-fold fewer deaths than the most transmissible wild type strains (from 80,000 to 500,000 deaths). Also, how an outbreak with seasonal influenza would influence global morbidity and mortality in the context of currently circulating strains is unknown. An unresolved question (which likely depends on the biology of the virus released and its similarity to currently circulating strains) is whether the laboratory-associated outbreak would replace the annual toll of seasonal influenza by supplanting circulating strains or would add to this toll. That is, if a laboratory-associated outbreak causes 300,000 deaths, would that be in addition to the several hundred thousand deaths expected annually or replace those expected deaths? Clearly, if a laboratory accident occurred with a wild type, circulating strain, the accident would simply mimic the commonplace occurrence of travel-associated spread of influenza.

This analysis demonstrates that enhancing the pathogenicity of a seasonal influenza strain increases the number of global deaths resulting from an outbreak significantly, largely due to the fact that the case fatality rate of unmodified seasonal influenza is very low. Increasing the case fatality rate from its highest level observed in seasonal influenza to that of 1918 pandemic influenza (5%), increases deaths by more than tenfold.

Increasing the transmissibility of seasonal influenza also increases the number of global deaths significantly, but to a lesser degree than increases in pathogenicity. Increasing the R_0 from 1.4 to 2.2 can double global deaths.

From this analysis, vaccines and antivirals have little influence on the global outbreak because of poor public health infrastructure and resource availability across most of the world. For this reason, the GoF phenotype leading to the evasion of the protection afforded by vaccination or antivirals does not significantly increase global consequences.

However, when the outbreak in North America is considered alone (Figure 6.39), vaccines and antivirals can reduce the deaths by an order of magnitude. This result may be surprising because the outbreak is with an unanticipated serotype so no effective vaccine would be available for months. For a GoF strain of influenza to overcome protection caused by a vaccine made specifically in response to the outbreak this strain is causing, it must be modified to overcome immunity caused by any vaccine, not just a vaccine matched to its serotype. Although the GoF literature describes how to alter the antigenic properties of influenza, no one has described an experiment that makes an influenza strain overcome protective vaccination regardless of its serotype. For this reason, only some GoF experiments leading to the evasion of induced immunity increase consequences.

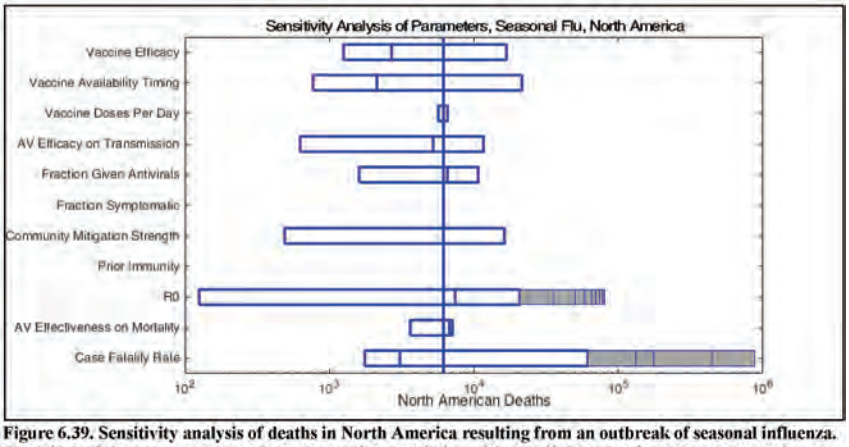

Figure 6.39. Sensitivity analysis of deaths in North America resulting from an outbreak of seasonal influenza. The width of the boxes corresponds to the median prediction of deaths if the value for that parameter is set to its lowest and highest level (and all other values are allowed to vary). Hollow boxes show the parameter value range for community control measures and wild type pathogens. Grey sections of the boxes show how increases in the transmissibility or pathogenicity beyond wild type levels affect consequences.

When considering North America alone, antivirals also can reduce deaths significantly, by about an order of magnitude. Although in a typical seasonal influenza outbreak, only about 5% of patients receive antivirals, federal caches of influenza antivirals could accommodate a much greater level of treatment and so overall death rates could drop significantly (largely through the prevention of secondary infections from those administered antivirals during treatment—compare the width of the bars for AV efficacy at preventing transmission versus AV effectiveness on mortality). For this reason, resistance to antivirals in a modified strain could increase the death toll of an influenza outbreak in the US by about an order of magnitude (fourth and fifth box from top in Figure 6.39) even though this phenotype would have negligible influence on the number of deaths globally (fourth and fifth box from top in Figure 6.38).

6.7.2 Pandemic Influenza Virus

Even if a wild type strain of pandemic influenza sparked a global outbreak, the consequences would eclipse those from all industrial accidents ever suffered. This section describes which GoF phenotypes would influence the consequences of a global outbreak of pandemic influenza strains. The GoF phenotypes relevant to an ongoing global outbreak are:

- The ability to overcome protective vaccination,
- The ability to overcome prior immunity (either natural or induced by previous vaccinations or infection by similar strains in the past),
- Resistance to antivirals,
- Transmissibility, and
- Pathogenicity (used here, case fatality rate).

As above the ability to evade diagnostics is of secondary importance to the effect of antivirals and vaccines and the GoF phenotypes of enhanced growth and adaptation to mammalian hosts are irrelevant to an ongoing outbreak.

To understand how various GoF phenotypes influence the consequence to a global outbreak of pandemic influenza, a sensitivity analysis was performed as described above (Figure 6.40). All parameters can be explored with this analysis simultaneously EXCEPT for prior/natural immunity in the population because the estimated R_0 of a disease is calculated given natural levels of immunity (that is, the value of these two parameters are linked). The ability of a pathogen to evade natural immunity is explored separately.

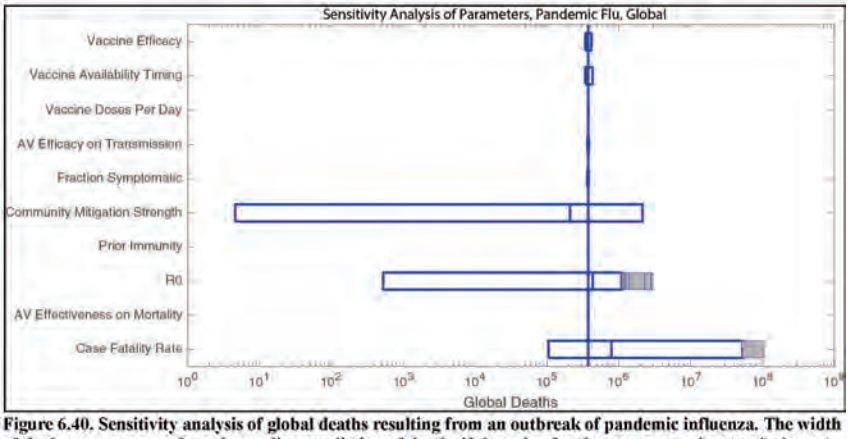

Figure 6.40. Sensitivity analysis of global deaths resulting from an outbreak of pandemic influenza. The width of the boxes corresponds to the median prediction of deaths if the value for that parameter is set to its lowest and highest level (and all other values are allowed to vary). Hollow boxes show the parameter value range for community control measures and wild type pathogens. Grey sections of the boxes show how increases in the transmissibility or pathogenicity beyond wild type levels affect consequences.

Firstly, this analysis demonstrates the great variability possible within the wild type strains that exist. The least deadly (non-attenuated) wild type strains are predicted to cause 400-fold fewer deaths globally than the most deadly wild type strains (from 100,000 to 50 million deaths). This result mirrors our previous observations from the recent 2009 pandemic and the 1918 pandemic, which demonstrated an enormous difference in their case fatality rate. The least transmissible wild type strains are predicted to cause 1,000-fold fewer deaths than the most transmissible wild type strains (from less than a thousand deaths to 1,000,000 deaths).

From this analysis, we note the GoF-related modification of pandemic influenza to increase transmissibility or pathogenicity may influence the global consequences. Vaccines and antivirals have little influence on the global outbreak because of poor public health infrastructure and resource availability across the world. For this reason, the GoF phenotype leading to the evasion of the protection afforded by vaccination or antivirals does not significantly increase global consequences.

When North America is considered alone, for pandemic strains, vaccine evasion and antiviral resistance influences potential deaths about tenfold (Figure 6.41).

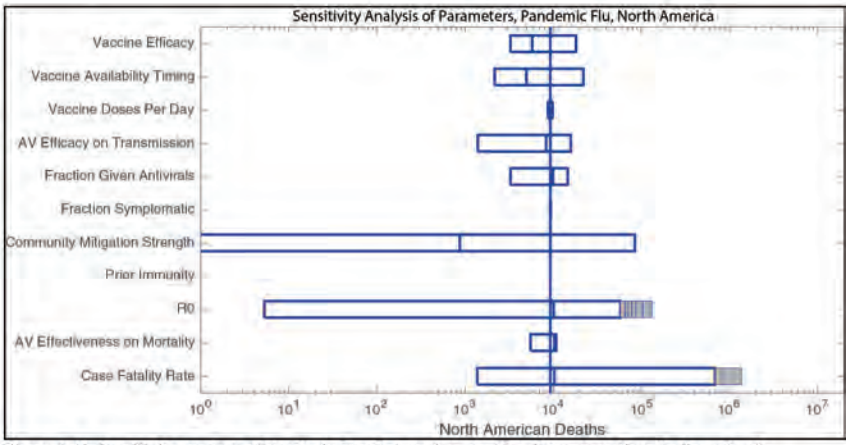

Figure 6.41. Sensitivity analysis of deaths in North America resulting from an outbreak of pandemic influenza. The width of the boxes corresponds to the median prediction of deaths if the value for that parameter is set to its lowest and highest level (and all other values are allowed to vary). Hollow boxes show the parameter value range for community control measures and wild type pathogens. Grey sections of the boxes show how increases in the transmissibility or pathogenicity beyond wild type levels affect consequences.

6.7.3 Avian Influenza Virus That is Transmissible Amongst People

Wild type strains of avian influenza are unable to cause a global pandemic unless they are transmissible amongst people. For this reason, the consequences of a global outbreak for GoF phenotypes other than transmissibility all must be considered in the context of a strain that is already modified to be highly transmissible. This interaction is explored below.

6.7.4 Coronaviruses

Even if a wild type strain of a SARS-like CoV sparked a global outbreak, the consequences would be significant. This section describes which GoF phenotypes would influence the consequences of a global outbreak caused by a SARS-like CoV. We focus on SARS-like CoVs because wild type MERS-CoV is not sufficiently transmissible in people to cause a global pandemic. If MERS-CoV were modified to be more transmissible, the resulting outbreak would resemble that caused by a SARS-like CoV. The GoF phenotypes relevant to an ongoing global outbreak are simply transmissibility and pathogenicity because there are no medical countermeasures to forestall the spread of the illnesses caused by the coronaviruses.

As above, the GoF phenotypes of enhanced growth and adaptation to mammalian hosts are irrelevant to an ongoing outbreak (unless they alter transmissibility or pathogenicity). To understand how various GoF phenotypes influence the consequence to a global outbreak of a SARS-like disease, a sensitivity analysis was performed as described above (Figure 6.42). As the data show, increasing transmissibility of SARS-CoV beyond wild type levels (R_0 of 1.6) can increase median global deaths predicted by several fold, a similar effect to increasing the pathogenicity. If the R_0 value of wild-type SARS-CoV is considered to be 3.0, further increases are of little consequence. Of note, variation in the estimates of wild type transmissibility of SARS-CoV can increase or decrease global deaths by 100,000-fold, showing how little effect a modification can have compared to natural variation (or imperfect epidemiological estimates). Similarly, the ability of the community to reduce their contacts for a significant period of time has a similar influence on the consequences of the outbreak. If the worst-case estimates for transmissibility for a SARS outbreak were used one could expect a global outbreak to kill tens of millions of people. Recall that since SARS is very susceptible to control measures, much of the difference in these estimates is likely due to the robustness of public health measures undertaken to curtail its spread.

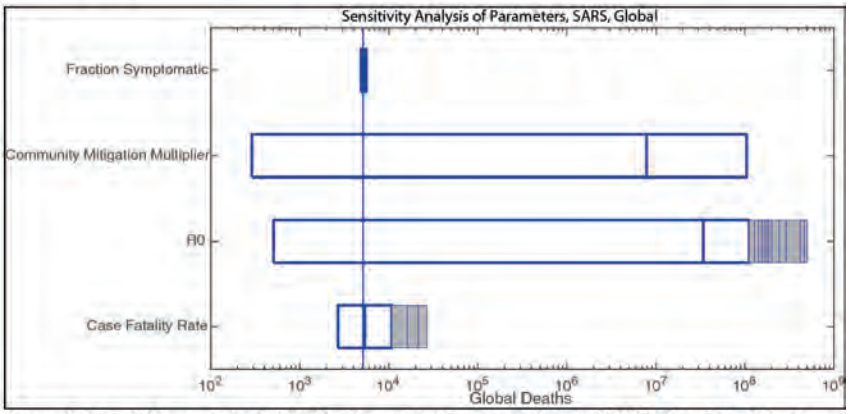

Figure 6.42 Sensitivity analysis of global deaths resulting from an outbreak of SARS. The width of the boxes corresponds to the median prediction of deaths if the value for that parameter is set to its lowest and highest level (and all other values are allowed to vary). Hollow boxes show the parameter value range for community control measures and wild type pathogens (R0 of no greater than 1.6). Grey sections of the boxes show how increases in the transmissibility or pathogenicity beyond wild type levels affect consequences.

Firstly, this analysis demonstrates the variability possible within the wild type strains that exist. The least deadly wild type strains are predicted to cause four-fold fewer deaths globally than the most deadly wild type strains (from 3,000 to 10,000).

A global outbreak of a SARS-like disease would differ from a global influenza outbreak in many ways, several of which are explicitly explored in this analysis (like case fatality rate, existence of medical countermeasures, etc.). Beyond these traits, SARS has a much longer incubation time (median of more than four days but a much greater average) than influenza and therefore a global outbreak of SARS would be much more protracted than an outbreak of influenza. Figure 6.43 shows when the peak number of daily cases of a SARS-like disease is reached compared to the initiation of the outbreak. For the smallest outbreaks, the peak is reached within the first 500 days. However, other outbreaks require many years to reach their peak in terms of cases per day. Clearly, the protracted nature of a SARS-like disease pandemic could put a greater strain on sustaining a response and, conversely, afford some additional opportunities for outbreak control compared to an influenza pandemic that circulates in less than a year. Given that an outbreak of this kind has never been experienced, the nature and effect of these possibilities cannot be quantified in the current modeling effort.

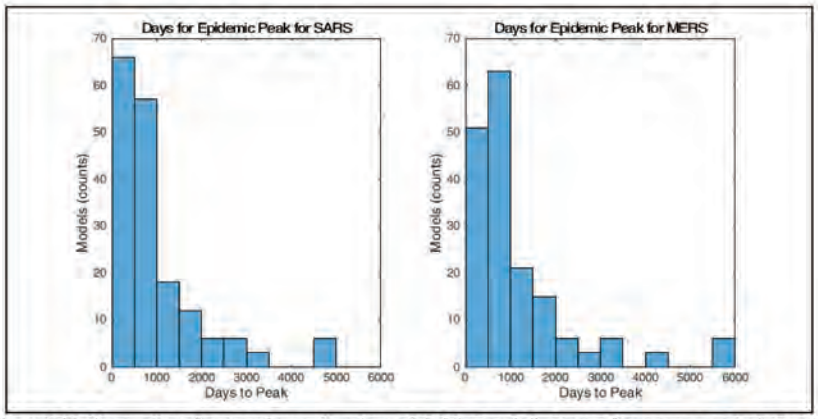

Figure 6.43. The number of coronavirus outbreaks modeled that peak (in terms of new cases per day) at any particular day after the global outbreak begins. To show the duration of truly global outbreaks, outbreaks that lead to less than one million infections are not shown.

The sections that follow provide a drill-down to describe HOW changes in any of the GoF phenotypes affect the consequences of a global outbreak.

6.7.5 Effect of Enhanced Transmissibility in Mammals on Consequences of a Global Outbreak Seasonal influenza

As discussed above, increasing the transmissibility of a seasonal influenza strain can double the global death toll. Figure 6.44 explores this relationship in more detail. These data show that increasing the transmissibility of seasonal influenza to match that of an average pandemic influenza outbreak (R_0 of 1.7) is sufficient to double the death toll and increases beyond that point do no further increase consequences significantly. For relatively poorly transmissible strains of seasonal influenza, increasing the transmissibility to the greatest levels observed for wild type strains (in blue on the left in Figure 6.44) can

increase global deaths by 50 fold if no social distancing measures are taken during the outbreak. Recall that community mitigation is a parameter that describes the actions taken by the public to reduce their contacts with potentially infected individuals (such as avoiding public gatherings and mass transit). Essentially, community mitigation reduces the ability of the disease to spread effectively in the population.

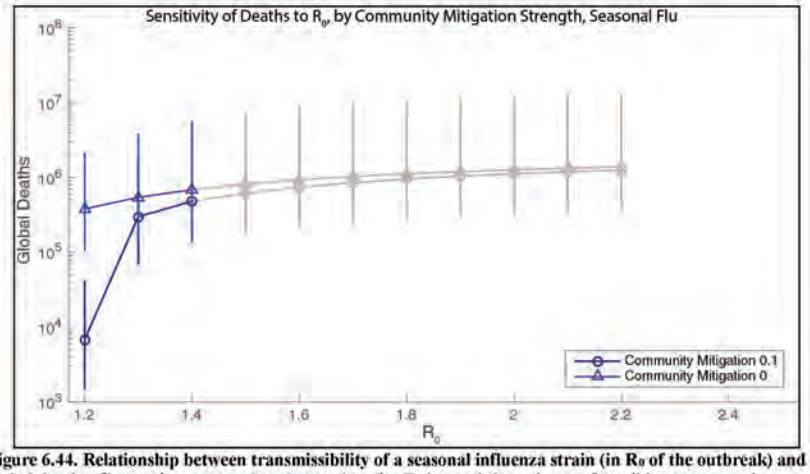

Figure 6.44. Relationship between transmissibility of a seasonal influenza strain (in R_0 of the outbreak) and global deaths. Grey points are used to show values for R_0 beyond the estimates for wild type seasonal influenza strains corresponding to the tornado plot in Figure 6.27. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.5.1 Pandemic Influenza

Increasing the transmissibility of a pandemic influenza strain can increase global risk if the wild type strain is poorly transmissible (such as 1918 H1N1 pdm due to the protection afforded by recently circulating strains). In contrast, if the strain is highly transmissible (like H2 strains) further increases in transmissibility are not significant. For strains with a R_0 of 1.2 (such as 1918 H1N1 pdm in today's population), any increase in transmissibility can increase global consequences by at least 100-fold if any community mitigation but the most stringent is assumed (even a reduction in contacts by 10%--community mitigation of 0.1). In contrast, for the most transmissible strains, increasing transmissibility increases global consequences only if the most severe community mitigation is assumed (a sustained reduction of contacts by 50%). Given that these outbreaks last many months, the ability for the community to sustain this level of social distancing is doubtful, especially given that this level of community mitigation has not been observed in any prior modern influenza outbreak. Figure 6.45 explores this relationship in more detail

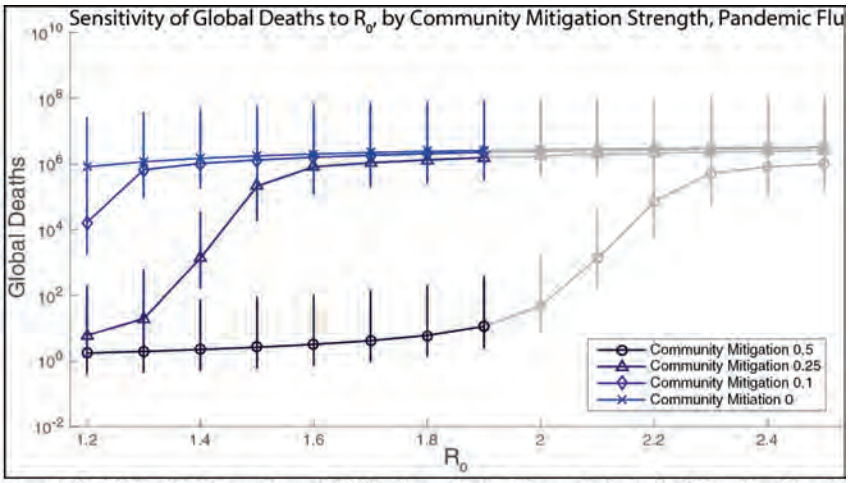

Figure 6.45. Relationship between transmissibility of a pandemic influenza strain (in R_0 of the outbreak) and global deaths for various levels of sustained community mitigation. Grey point are used to show values for R_0 beyond the estimates for wild type pandemic influenza strains and correspond to colors in Figure 6.29. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.5.2 Avian Influenza

In Figure 6.46, we show the relationship between R_0 and global cases of avian influenza for four levels of community mitigation. With a novel, highly pathogenic illness, we can expect the public to significantly change their behavior, as was observed in the SARS outbreak in Canada. However, we lack the data to predict to what degree social distancing can be implemented and for what period of time. Figure 6.46 shows, however, that unless very significant levels of community mitigation can be sustained for a very long time, the number of global cases significantly increases as the R_0 of an avian influenza strain approaches that of seasonal influenza. Increasing the R_0 past 1.5 (which is typical for pandemic influenza strains) has no further effect on consequences. If, however, community mitigation can be sustained at a very high level, then to significantly increase global consequences, the avian influenza strain must be more transmissible than any pandemic influenza strain ever observed. Because the ability of the community to reduce their contacts for a significant period of time is dubious, we presume that the increase of the transmissibility of avian influenza to that of seasonal influenza significantly drives the potential consequences of an outbreak.

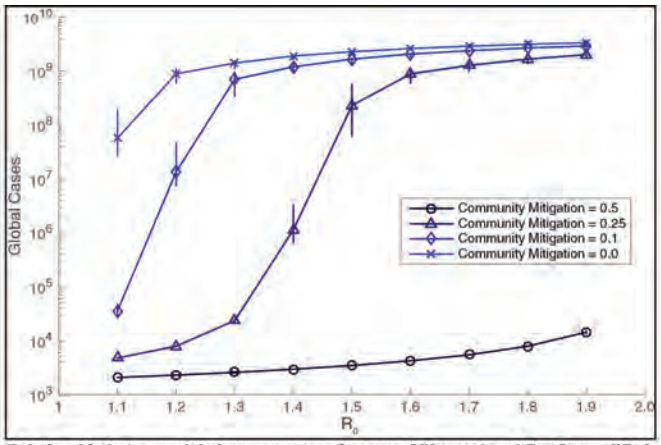

Figure 6.46. Relationship between global consequences (in term of illnesses) and R_0 of a modified avian influenza virus and the strength of community mitigation. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.5.3 Coronaviruses

Figure 6.47 shows the relationship between R_0 and global cases of a SARS-like CoV for three levels of community mitigation. The data show that for wild type strains of SARS-like CoV, the virus is already sufficiently transmissible ($R_0 > 1.4$) to maximize global deaths unless very significant levels of community mitigation can be sustained for a very long time. Figure 6.47 shows results for a SARS-like CoV, but the results for a MERS-like CoV are nearly the same (not shown). That being said, because MERS-CoV is less transmissible than SARS-CoV, a greater increase in transmissibility over a wild type strain is required to produce the same increase in risk. Because the ability of the community to reduce their contacts for the years required for a global outbreak to run its course is unknown, these data suggest that SARS-like CoVs are already sufficiently transmissible to maximize a global outbreak and modifications that increase transmissibility are of little additional risk. Notably, if wild type SARS-CoV already is extremely transmissible ($R_0 > 2.0$) as some have suggested, then even sustained and robust community mitigation will not limit the outbreak. If this were the case, further increases in transmissibility would not increase risk.

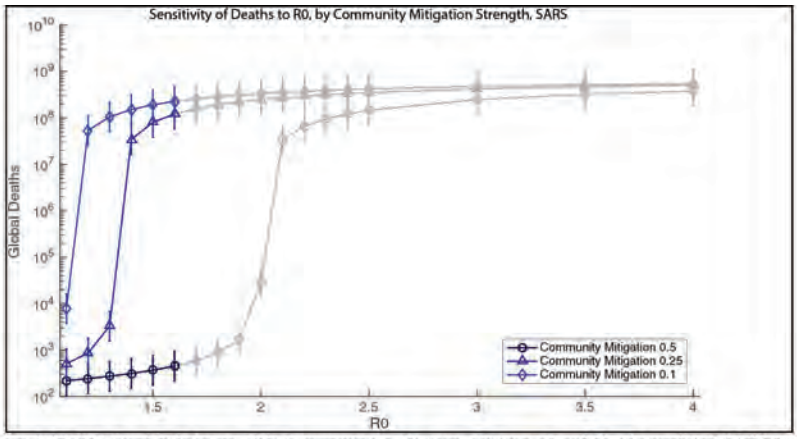

Figure 6.47. Relationship between global consequences (in term of illnesses) and R_0 of a modified SARS-like CoV and the strength of community mitigation. Strains modified to increase transmissibility beyond estimates for wild type SARS-CoV (here 1.6) are shown in grey. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.6 Effect of Enhanced Pathogenicity on Consequences of a Global Outbreak

6.7.6.1 Seasonal Influenza

Because of the low case fatality rate of typical seasonal influenza strains, increasing the pathogenicity of these strains can significantly increase the predicted global death toll (Figure 6.48). These data show that, as expected, increasing the case fatality rate by a factor of 10 or 100 increases the global deaths correspondingly. An increase of this magnitude would be reflected by the modification of a typical seasonal influenza strain to have the pathogenicity of the 1918 pandemic strain.

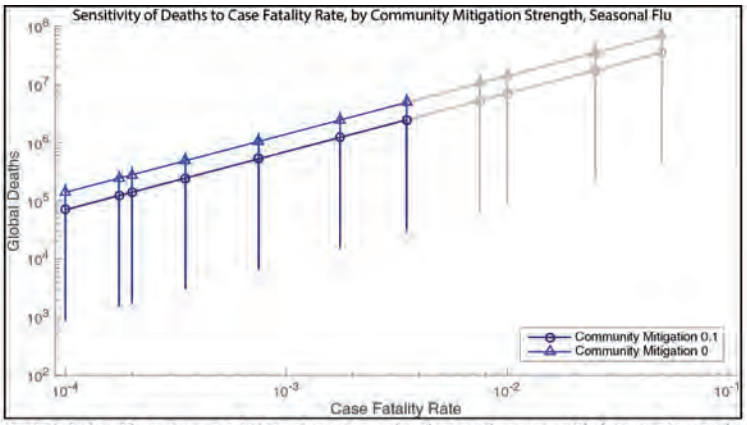

Figure 6.48. Relationship between global deaths and case fatality rate for seasonal influenza. Grey points are used to show values for R_0 beyond the estimates for wild type seasonal influenza strains corresponding to the tornado plot in Figure 6.27. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.6.2 Pandemic Influenza

Because the wild type 1918 pandemic influenza strain had a high case fatality rate, increasing this rate by a factor of 100 is impossible. Figure 6.49 shows the effect on global deaths of doubling the case fatality rate of a pandemic strain to be 10% (double that of the wild type 1918 strain). These data show that, as expected, doubling the case fatality rate doubles the global deaths correspondingly. Death rates beyond 10% have been observed in avian influenza strains only and then only rarely.

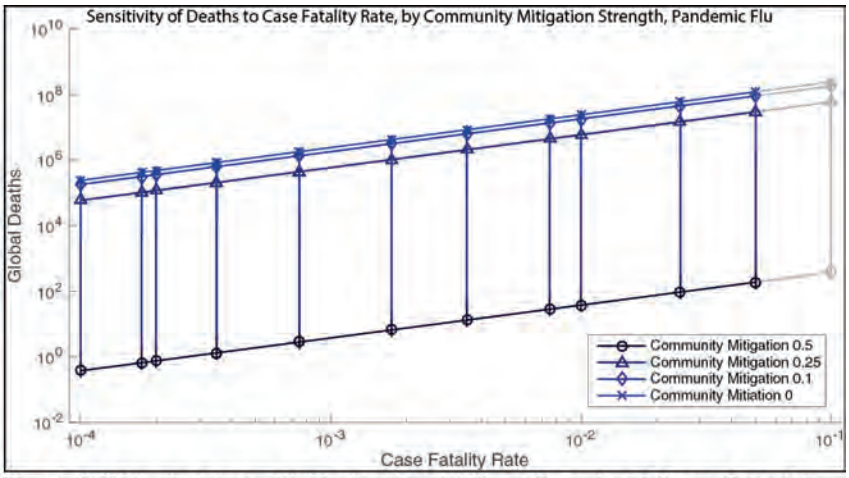

Figure 6.49. Relationship between global deaths and case fatality rate for pandemic influenza. Grey points are used to show values for R_0 beyond the estimates for wild type seasonal influenza strains corresponding to the tornado plot in Figure 6.27. Because the wild type 1918 pandemic strain has a case fatality rate of 5%, much of this graph is occupied by data reflecting wild type strains. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.6.3 Avian Influenza

If a strain of avian influenza that is already modified to be highly transmissible in people was further modified to be more pathogenic in people, the number of deaths is expected to increase. The natural range of pathogenicity in wild type strains of avian influenza is immense, from those that produce no clinical symptoms in humans to those that kill about half of those with recognized illness. For this reason, the GoF study that increases risk most is one in which the already pathogenic strain is made more transmissible while pathogenicity is maintained, not a GoF study in which pathogenicity is increased. However, as shown in Figure 6.50, below, expected global deaths increase linearly with increases in pathogenicity. Figure 6.50 also confirms how much an influence contagiousness has on consequences, as increasing the transmissibility beyond an R_0 of 1.1 increases deaths by at least 10,000 fold.

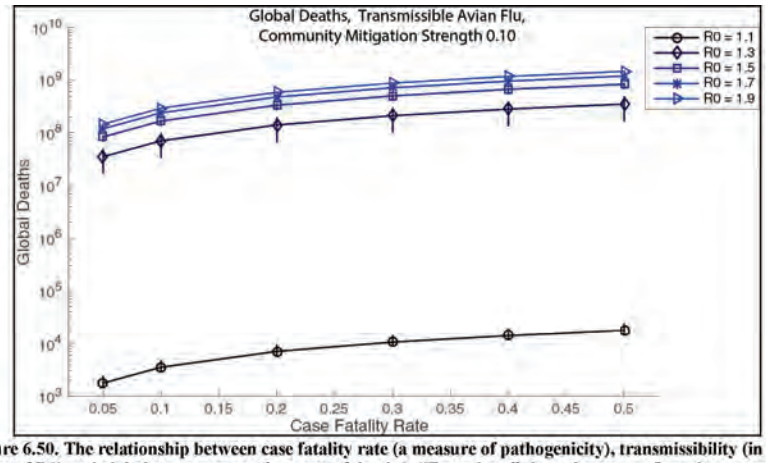

Figure 6.50. The relationship between case fatality rate (a measure of pathogenicity), transmissibility (in terms of R0) and global consequences (in terms of deaths). "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.6.4 Coronaviruses

Modifications to increase the pathogenicity (in this case, the case fatality rate) of a SARS-like CoV have the expected outcome in terms of global deaths as shown in Figure 6.51, in that doubling or tripling the rate of death doubles or triples global deaths.

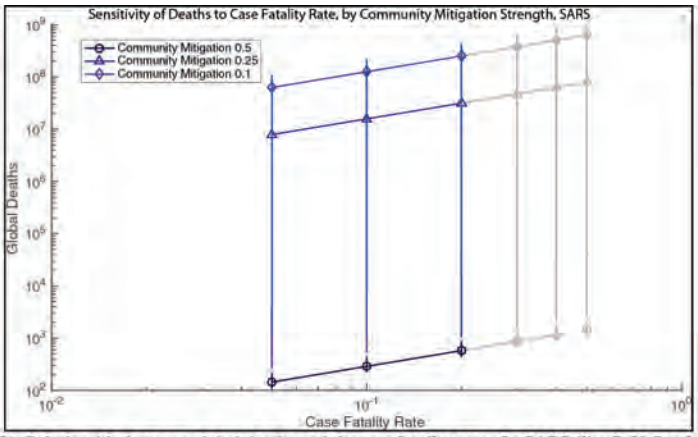

Figure 6.51. Relationship between global deaths and the case fatality rate of a SARS-like CoV. Strains modified to increase pathogenicity are shown in grey. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.7 Effect of Countermeasures Evasion on Consequences of a Global Outbreak

6.7.7.1 Seasonal Influenza

If the strain involved in the laboratory released were able to overcome protective vaccination, the outbreak in North America would cause up to four-fold more deaths (Figure 6.52—vaccine efficacy dropping from 0.6 or 0.4 to 0). Recall that the state of the public health infrastructure in the majority of the world is so parlous that vaccines do not appreciably affect global death rates for influenza, so this risk is realized only by high income countries. Also, this risk is realized only if the outbreak is caused by a strain of influenza that can overcome protective immunity afforded by any vaccine (instead of simply changing the antigenic properties of the virus) because even if a novel strain has unprecedented antigenic properties, a vaccine developed in the midst of an outbreak would be raised to the strain causing the nascent outbreak. For these reasons, this GoF trait poses little overall biosafety risk.

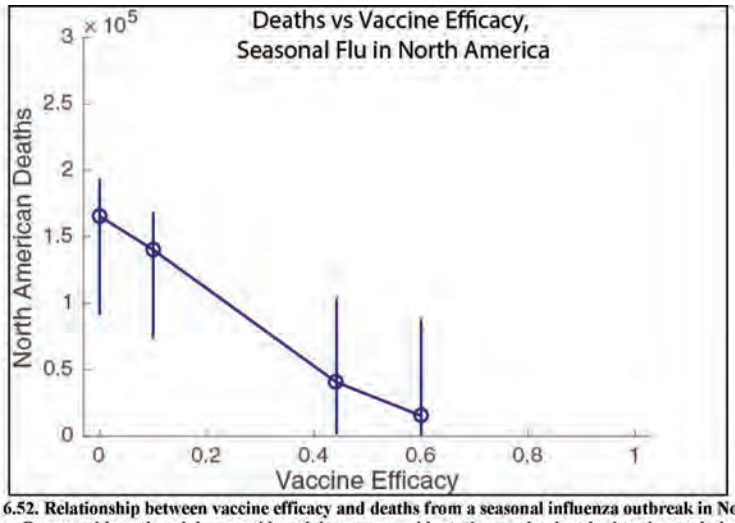

Figure 6.52. Relationship between vaccine efficacy and deaths from a seasonal influenza outbreak in North America. Because this outbreak is caused by a laboratory accident, the vaccine is raised to the strain involved in the outbreak soon after the outbreak occurs. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

In a typical influenza seasons, only approximately five percent of patients receive antivirals. If this level of antiviral distribution is used in the face of an outbreak caused by a laboratory accident, very few lives are saved by antivirals and therefore antiviral resistance has limited influence on risk (Figure 6.53—darker green line). However, the US holds a very large federal cache of antivirals that could be used to provide treatment for many victims in a serious influenza epidemic. One may presume that if a global outbreak were caused by an accident in a US laboratory, this cache would be deployed and used aggressively. In this case, antivirals can significantly reduce risk of an outbreak by preventing the onward transmission of influenza (Figure 6.53—light green line). Conversely, a seasonal influenza strain that is antiviral resistant could vitiate the protection afforded to the public by antivirals and could increase the consequences of an outbreak in North America by five-fold. We do not know how many other countries have similar large caches of antivirals so we cannot determine if this risk increase would be shared by the rest of the high income countries.

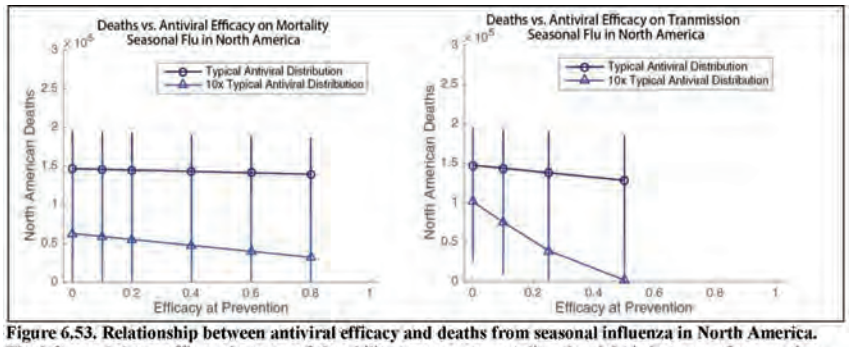

Figure 6.53. Relationship between antiviral efficacy and deaths from seasonal influenza in North America. The left panel shows efficacy in terms of the ability to prevent mortality, the right is in terms of preventing onward transmission. Typically, only about 5% of influenza patients receive antivirals. However, the US has a large cache of antivirals that could be used in case of an emergency. Typical use and possible use are shown in the graph. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.7.2 Pandemic Influenza

If the strain involved in the laboratory released were able to overcome protective vaccination, the outbreak in North America would cause up to four-fold more deaths (Figure 6.54—vaccine efficacy, defined by the percent reduction in infection risk for a vaccinated individual compared to an unvaccinated individual, dropping from 0.6 or 0.4 to 0). Recall that the state of the public health infrastructure in the majority of the world is so parlous that vaccines do not appreciably affect global death rates for influenza, so this risk is realized only by high income countries. Also, this risk is realized only if the outbreak is caused by a strain of influenza that can overcome protective immunity afforded by any vaccine (instead of simply changing the antigenic properties of the virus) because the vaccine would be raised to the strain causing the nascent outbreak. For these reasons, this GoF trait poses little overall biosafety risk.

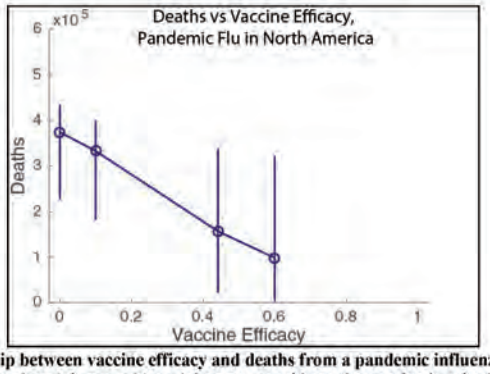

Figure 6.54. Relationship between vaccine efficacy and deaths from a pandemic influenza outbreak in North America. Because this outbreak is caused by a laboratory accident, the vaccine is raised to the strain involved in the outbreak soon after the outbreak occurs. "Error bars" show the range of results across 80% of the

parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

If only 5% of the population receives antivirals, then risk is barely mitigated (Figure 6.55—darker blue line). If antivirals were more widely distributed, these countermeasures can reduce risk of an outbreak by two- to four-fold by preventing the onward transmission of influenza and by preventing mortality (Figure 6.55—light blue line). Conversely, a pandemic influenza strain that is antiviral resistant could vitiate the protection afforded to the public by antivirals and could increase the consequences of an outbreak in North America by two-to four-fold. We do not know how many other countries have similar large caches of antivirals so we cannot determine if this risk increase would be shared by the rest of the high income countries.

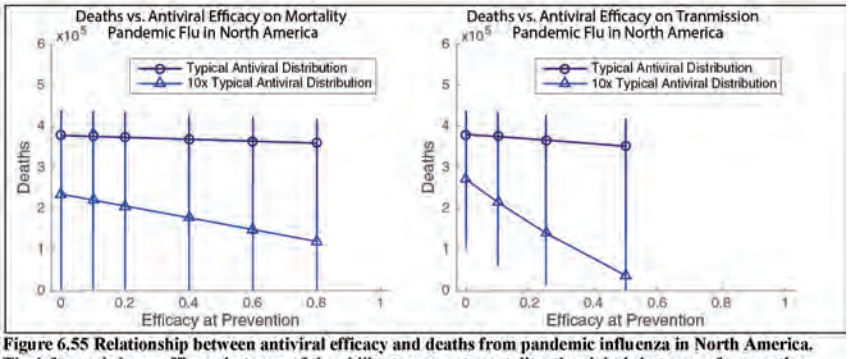

Figure 6.55 Relationship between antiviral efficacy and deaths from pandemic influenza in North America. The left panel shows efficacy in terms of the ability to prevent mortality, the right is in terms of preventing onward transmission. Typical use and possible use are shown in the graph. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented).

6.7.7.3 Avian Influenza

An unexpected outbreak of avian influenza that is highly transmissible amongst people would be very difficult to control with vaccination. The disease will have spread significantly by the time a protective vaccine could be developed, tested, made in quantity and deployed. For this reason, as shown in Figure 6.56, below, the efficacy of the vaccine (and therefore, the ability of the pathogen to evade protective vaccination), matters only for a narrow range of R_0 values for avian strains. North America is shown because this region has greater resources and capacity than the world as a whole so that vaccines can show some efficacy. If the strain is highly transmissible, then vaccination comes too late to prevent a significant number of deaths. If the strain is as transmissible as the least transmissible seasonal influenza strains, then community mitigation is sufficient to contain the outbreak to a relatively low level without vaccination.

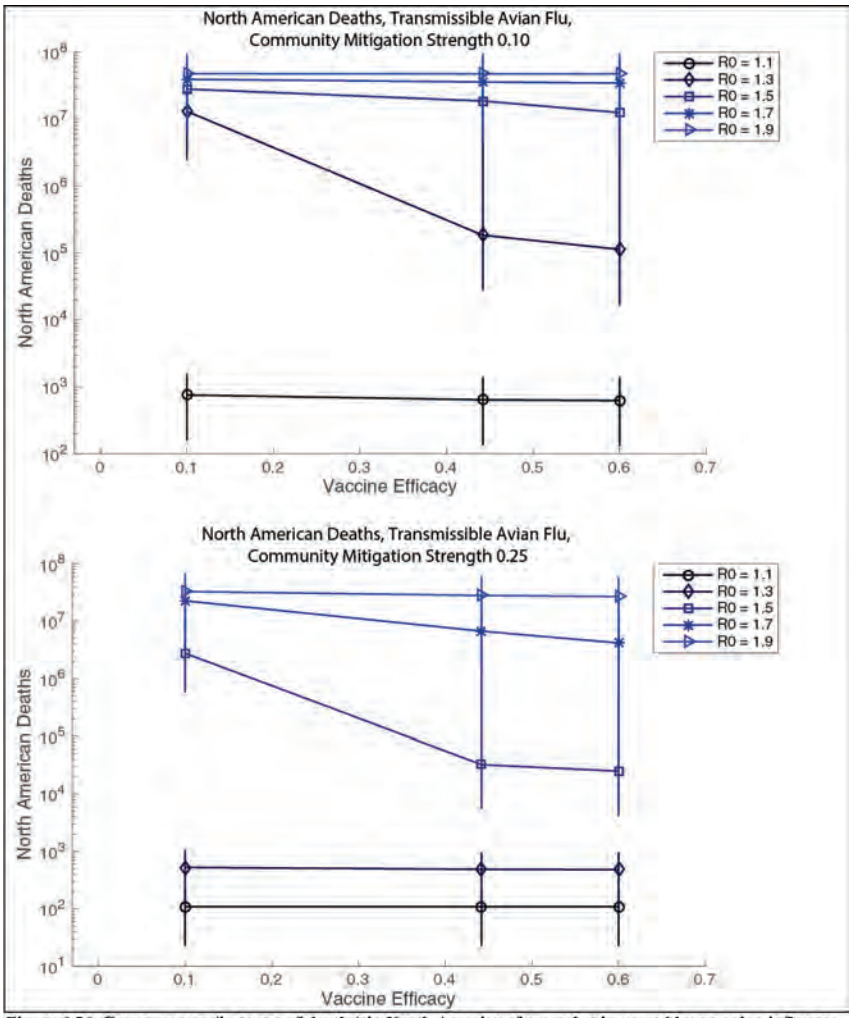

Figure 6.56. Consequences (in terms of deaths) in North America of a pandemic caused by an avian influenza strain modified to be highly transmissible amongst people as a function of vaccine efficacy and transmissibility. "Error bars" show the range of results across 80% of the parameter values explored in the analysis (the parameter values that cause the highest and lowest 10% of results are not represented). The panel above shows a modest level of community mitigation sustained throughout the pandemic, and the panel below shows a more robust level of community mitigation sustained through the pandemic.

Two critical points must be made. Firstly, because a vaccine will be developed for the serotype driving the outbreak, the evasion of a vaccine is only relevant if the strain is modified to evade protection by any vaccine, regardless of the antigenic properties of the virus. Secondly, predicting how transmissible an avian strain could become is difficult. Although seasonal influenza strains are highly transmissible, an avian strain could, theoretically, become as transmissible as a pandemic strain if much of the increase in transmissibility of pandemic strains over seasonal strains is due to the lack of protective innate or residual immunity in the population. For this reason, the value of protective vaccination against an unexpected outbreak caused by an avian strain is very difficult to predict with certainty.

In summary, two facts significantly limit the risk posed by a transmissible avian strain of influenza that can evade vaccination. Firstly, a narrow combination of phenotypes and control measures are necessary for vaccines to have a significant effect on the outbreak even in North America (where the response capacity is much greater than the world as a whole). Secondly, to affect risk at all, the strain must be able to overcome protective vaccination regardless of the serotype of the virus. Although this modification poses a biosecurity risk (see below), it is not the subject of active research (and also of dubious scientific benefits) and so poses little biosafety risk.

6.7.7.4 Coronaviruses

Currently, no countermeasures specific to infections by the coronavirus are used to treat illnesses caused by this pathogen or prevent the ongoing spread of an outbreak caused by this pathogen. For this reason, this phenotype has no influence on risk.

6.7.8 Effect of Evasion of Natural/Residual Immunity on Consequences of a Global Outbreak

6.7.8.1 Seasonal Influenza

As mentioned above, the baseline sensitivity analysis does not investigate the sensitivity to innate/residual immunity in the population, which can be significant for seasonal influenza strains, because population immunity is already accounted for in the effective R_0. In Figure 6.57 below, we investigate how changes in innate or residual immunity affects global deaths.

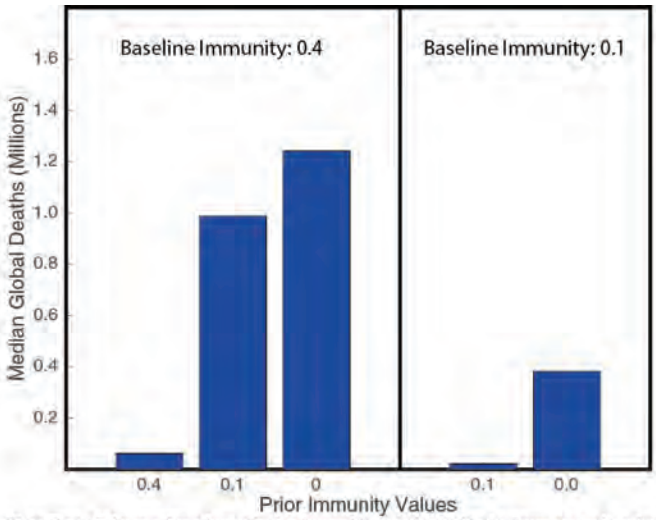

Figure 6.57. The effect of the evasion of population immunity on global deaths from an outbreak of seasonal influenza. The result for the baseline parameter value for prior immunity is the leftmost column in each panel. In the left-hand panel, the baseline assumption is that 40% of the population is protected against infection with a wild type strain. The graph shows the increase in the number of deaths when a strain (with the same R_0 value) were able to overcome most of the immunity (so that only 10% of the population were immune) or overcome all immunity. In the right-hand panel, the baseline assumption is that 10% of the population has immunity to the wild type strain. The graph shows the increase in number of deaths when the strain is modified to overcome all immunity.

This analysis demonstrates that the evasion of pre-existing immunity can increase global deaths by ten-fold, if the population has a high level of residual immunity (as is likely for seasonal influenza since prior vaccination or illness provides some protection against new strains). Similar to R_0, this parameter influences the global outbreak by enabling the disease to spread more quickly (because each contact is more likely to result in an infection) and eventually infect a larger number of people worldwide. Pre-existing immunity can protect a significant proportion of the population if the strain released is similar (or identical) to a strain of influenza that recently circulated, which is one reason why this parameter is influential. If the population exhibited relatively low levels of prior immunity, then evasion of prior immunity has a smaller influence on consequences.

6.7.8.2 Pandemic Influenza

As mentioned above, the baseline sensitivity analysis does not investigate the sensitivity to innate/residual immunity in the population because population immunity is already accounted for in the effective R_0. In Figure 6.58 below, we investigate how changes in innate or residual immunity affects global deaths.

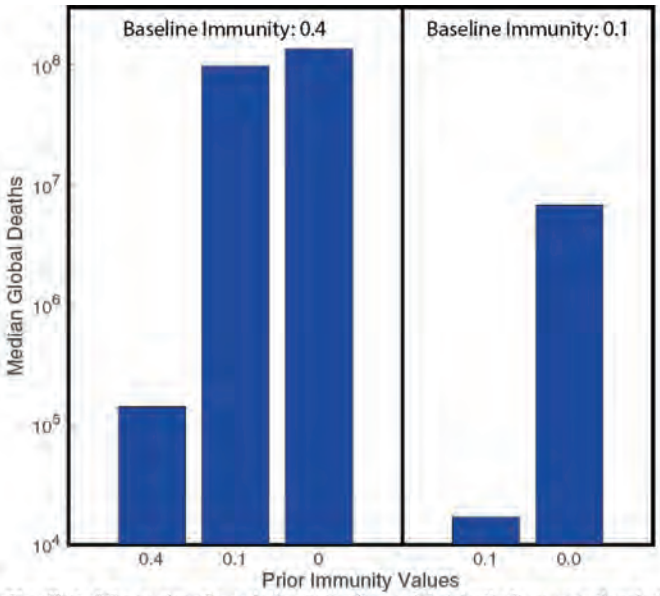

Figure 6.58. The effect of the evasion of population immunity on global deaths from an outbreak of pandemic influenza. The result for the baseline parameter value for prior immunity is the leftmost column in each panel. In the left-hand panel, the baseline assumption is that 40% of the population is protected against infection with a wild type strain. The graph shows the increase in the number of deaths when a strain (with the same R_0 value) were able to overcome most of the immunity (so that only 10% of the population were immune) or overcome all immunity. In the right-hand panel, the baseline assumption is that 10% of the population has immunity to the wild type strain. The graph shows the increase in number of deaths when the strain is modified to overcome all immunity.

This analysis demonstrates that the evasion of pre-existing immunity can greatly increase global consequences for those pandemic strains against which the population has a significant immunity (1918 H1N1 pdm and 2009 H1N1 pdm). In fact, this parameter can increase the expected global deaths from an outbreak of 1918 H1N1 pdm by a factor of 1,000. Even if pre-existing immunity is minimal but non-zero, the expected deaths caused by an outbreak that evades this immunity increases by more than 100-fold.

6.7.8.3 Avian Influenza

Exposure to avian influenza strains is so rare in human populations that very few people have residual immunity to this pathogen. For this reason, evasion of residual immunity has no influence on risk.

6.7.8.4 Coronaviruses

Exposure to a coronavirus is so rare in human populations that very few people have residual immunity to this pathogen. For this reason, evasion of residual immunity has no influence on risk.

6.8 Supporting an Estimate of Absolute Risk

This assessment was designed to evaluate the increase in risk caused by the creation of strains of pathogens with GoF traits compared to wild type pathogens. This approach enabled the assessment to capitalize on the strengths of the available data and minimize the importance of the weaknesses. Sufficient biomedical and epidemiological evidence exists to develop robust models of the initiation of an outbreak from the primary to the secondary cases and the expansion of this outbreak within a community to eventually spark a global pandemic. In contrast, very little data exists on human reliability in life science laboratories, which drives the probability that laboratory acquired infections occur in the first place. Fortunately, the accidents that humans cause (or contribute to) in the laboratory are the same regardless of the pathogen manipulated. That is, workers may overfill a centrifuge tube with the same frequency regardless of the pathogen in the tube or will slip while working with scissors during a necropsy with the same frequency regardless of the pathogen studied. Because the absolute rate at which these accidents happen and cause infections is not supported by robust data, absolute estimates of the rate of laboratory acquired infections cannot be made using the method described in this report.

However, to provide a context for the increase in risk suffered, absolute risk estimates are desired. For this reason, the historical rate of laboratory acquired infections could be used to predict a reasonable upper bound for the frequency with which these incidents occur. However, the research team is unaware of any laboratory acquired infections in laboratories that study influenza or coronaviruses, and so an absolute risk analysis will have at its foundation a weak estimate of the frequency at which laboratory acquired infections occur. That being said, this historical rate of laboratory infections can then be combined with calculated rates of laboratory acquired infections leading to secondary infections, local outbreaks, and global pandemics from this assessment to produce an estimate of absolute risk.

The return frequency of laboratory acquired infections (LAIs) was estimated for several hypothetical historical LAI counts, presuming that some historical LAIs may have gone undetected or unreported. LAI frequency was modeled using a binomial distribution, with the number of trials set to the number of laboratory-years (i.e., the number of laboratories working with the viruses times the observation period), and the number of "successes" equal to the number of LAIs. For influenza, 100 labs[364] and an observation period of twenty years (for a total of 2,000 lab-years) was assumed because there has been roughly 20 years since the expansion of the life science research in the mid-1990s. This time period also coincides with a wave of construction of modern biocontainment facilities that better represent the safety conditions of today's laboratories than previous laboratories.

Shown are the limits of the two-sided 80% confidence interval on the expected LAI frequency, estimated using a Clopper-Pearson interval.[365] The maximum likelihood estimate (MLE) of the frequency with which an LAI would occur (the return frequency) was computed as the number of laboratory years divided by the number of LAIs. Note that, for zero observed LAIs, the minimum and MLE return rate approach infinity and are not plotted.

The project team knows of no laboratory acquired infections involving any one of these laboratories.[366] This lack of a laboratory acquired infection could be due to the fact that none have occurred in that time frame or that some have occurred but the project team does not have access to the reports or data. Figure 6.59 shows the limits of the 90% confidence interval (90 out of 100 times, LAIs would happen, on

---

[364] The exact number of laboratories does not significantly influence absolute risk (the per-laboratory rate decreases but the absolute rate of an accident across all laboratories does not change).

[365] Newcombe RG (1998) Two-sided confidence intervals for the single proportion: comparison of seven methods. *Statistics in medicine* 17: 857-872.

[366] At least one parenteral exposure to H5N1 has occurred, and this worker was isolated, but never became ill, probably because influenza is a respiratory pathogen and cannot infect muscle.

average, less often) and maximum likelihood estimate of the return period of laboratory acquired infections given that zero to ten infections have occurred in the past 20 years in the approximately 100 laboratories.

Across all 100 laboratories, a laboratory acquired infection could be expected as frequently as once every 8.5 years (if no infections have occurred in the last 20 years) to as little as every 200 years (if one infection occurred). If the assumption is made that three LAIs have surreptitiously occurred, then an LAI is expected to occur from once every three years to once every 20 years.

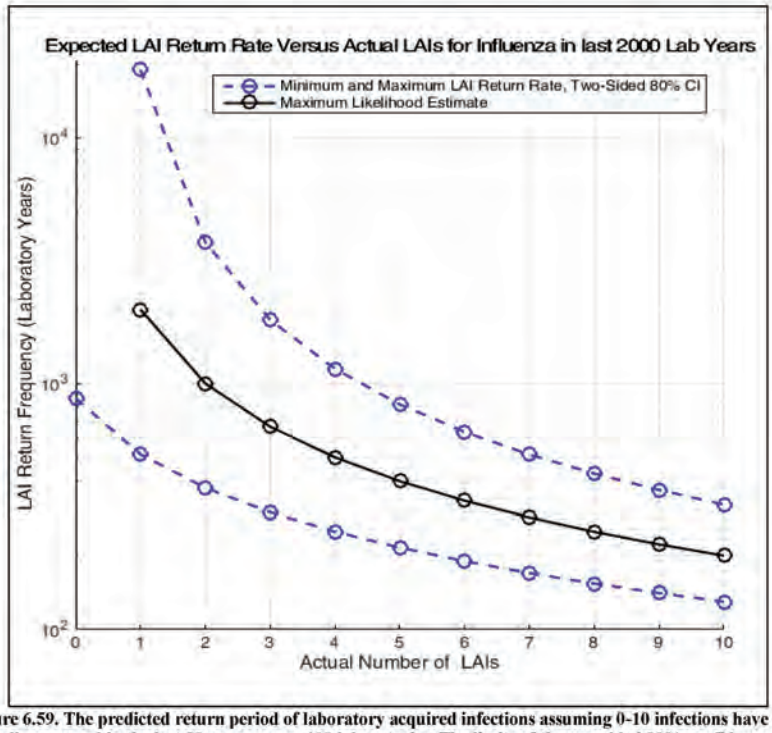

Figure 6.59. The predicted return period of laboratory acquired infections assuming 0-10 infections have actually occurred in the last 20 years across 100 laboratories. The limits of the one-sided 90% confidence interval of the maximum rate (bottom line) was used to produce an estimate of the return period that would be greater than 90 out of 100 actual values of the frequency given the observations, whereas the maximum likelihood estimate and limits of the one-sided 90% confidence interval of the minimum rate (top line) are also shown.

The quantitative analysis in this report estimates that a small minority of these infections would start a local outbreak and a minority of these outbreaks would seed a global pandemic.

For seasonal influenza, the analysis presented above suggests that only 0.4% of LAIs with seasonal influenza are predicted to cause a global pandemic (assuming the strain has not recently circulated, in which case, the probability would be even less). Because most of the 100 laboratories working on the pathogens assessed in this report are studying seasonal influenza, this analysis suggests that a global pandemic would be caused by a laboratory accident in the US once every 2,000-50,000 years (if essentially no LAIs have occurred in influenza laboratories in the past 20 years). If instead the assumption is made that three LAIs have surreptitiously occurred, a global pandemic could be triggered once every 750-5,000 years. It is worthy to note that viruses were characterized much less than 750 years ago, so it cannot be stated with any certainty that these pathogens will be studied under similar containment conditions for long enough into the future for an accident to be likely to occur even once. Moreover, the true consequence of a seasonal influenza outbreak caused by a laboratory accident is unclear. Although predictions can be made about the illnesses and deaths that would be caused, it is unknown how this outbreak would influence the evolution and spread of other influenza strains and if these laboratory-associated infections would supplant or supplement those expected on an annual basis. This caveat aside, the analysis predicts 100,000-4,000,000 deaths to occur from a global outbreak of a wild type seasonal influenza strain, depending on the pathogenicity and transmissibility of the strain.

Considering the other influenza viruses in this study, a historical analysis predicts that LAIs would occur with a similar frequency assuming that no infections have occurred (the per-laboratory rate of LAIs increases but fewer laboratories study these pathogens). This result is obviously counterfactual because these pathogens are manipulated at a greater containment level than wild type, seasonal influenza viruses to decrease the probability of a LAI. That being said, a conservative estimate predicts that laboratory acquired infections occur at the same rate as for seasonal influenza viruses. The analysis presented above suggest that only 1.5% of LAIs with pandemic influenza are predicted to lead to global outbreaks. Combined with the predicted return frequency of LAIs given no LAIs in the last 20 years, a global pandemic caused by research on pandemic influenza viruses is expected every 560-13,000 years. Assuming that no LAIs have occurred with the deadliest pandemic strains is reasonable because, it would be widely known if several laboratory accidents occurred. An accident that sparks an epidemic with a strain as deadly as the 1918 pandemic strain but as transmissible as the 1957 strain could cause up to 80 million global deaths according to the analysis presented above. If, conversely, the accident occurred with a strain similar to the 2009 pandemic strain, it would resemble an accident with seasonal influenza.

Wild type avian influenza strains are not transmissible enough among people to cause a significant local outbreak and therefore no global outbreak is possible. Assuming the same return frequency of laboratory acquired infections for avian influenza as predicted for seasonal influenza, a laboratory worker is expected to fall ill once every three to nine years. For the most pathogenic strains, this worker has a significant chance of dying but the outbreak is likely to extend no further than that one case.

Given that SARS-CoV has been studied for only a decade, the historical record of no laboratory accidents once again suggests that LAIs occur more frequently in coronavirus laboratories at BSL-3 than in laboratories that study seasonal influenza at BSL-2, which is obviously wrong. If, conservatively, the estimate is made that LAIs with SARS-CoV occur as frequently as influenza, a LAI is expected to occur once every 8.5 years (given the seriousness of SARS, LAIs are likely to have been reported so it is safe to assume that no LAIs have occurred yet with this pathogen in the US). The best estimates for the transmissibility of SARS-CoV and its susceptibility to control measures suggest that there is no chance that this outbreak would spark a global pandemic (and SARS-CoV is more transmissible than MERS-CoV). Most of these LAIs would lead to no further infections, however, some would lead to the infection of a handful of other individuals.

6.9 Using the Parametric Risk Assessment: Example Calculation

By design, the biosafety risk assessment is broad and provides data to understand how risk changes if a wild type pathogen is manipulated in one of a variety of ways. This section provides an example illustrating how to simply use the information contained in this report to assess the risk posed by a *particular* manipulation. This example compares the risk of research on two possible modified strains to a wild type strain of influenza (called Strain 1). The example assumes that the strain has not circulated recently so that it itself has some real biosafety risk. This example will use parameter values typical for a wild type seasonal influenza strain as a baseline, which is described by the following parameters:

- Transmissibility: R_0=1.3,
- Pathogenicity: Case fatality rate of 0.001,
- Antiviral sensitivity: (efficacy at preventing transmission=0.25, efficacy at preventing death=0.4),
- Vaccine protection: (efficacy of 0.5 at preventing infection), and
- Infectivity: Set to seasonal influenza (ID_{50} less than 10pfu).

This example uses two modified strains. Strain 2 is a GoF strain of seasonal influenza that is exactly like the wild type strain, except that it is as transmissible as a strain pandemic influenza (R_0=1.7). Strain 3 is an attenuated strain of seasonal influenza that is exactly like the wild type strain, except that it has a case fatality rate of 0.0001.

The modeling completed enables a complete assessment of how any combination of parameter values that describe the pathogen and control measures influences risk, however, all possible combinations of these values and their influence on risk cannot be shown concisely in a report. Instead, static slices through this very complex risk space are taken and shown as two-dimensional figures in this report that explore the effect of changing one parameter while allowing all others to vary. That is, using this report, phenotypes must be assessed individually. The reader will note that the baseline results change regarding which trait is being considered for the same strain (that is, which parameter is held at a particular value while all others are allowed to vary). This phenomenon is expected because the figures show the median and 80th percentile results for all of the parameters that COULD describe a wild type strain and a modified strain (and the same range of values for the control measures). This parameter range will obviously change depending on which trait is held constant.

6.9.1 Step 1: Determine if the Probability of the Pathogen Escaping the Laboratory Changes

To determine how the probability of a pathogen escaping the laboratory changes as a pathogen is modified, refer to Section 6.4.4, specifically 6.4.4.1 for seasonal influenza. Table 6.3 shows how any trait affects this probability. Neither of the traits considered in this example influence the probability that a laboratory incident would lead to escape of the pathogen from the laboratory.

Recall that, although the analysis developed for this study will not permit an estimation of how frequently laboratory accidents lead to laboratory acquired infections that spark a local outbreak, historical rates of accidents suggest that a local outbreak would be sparked by a laboratory acquired infection about once every 500-10,000 years.

6.9.2 Step 2: Determine the Change in the Probability of a Resulting Outbreak Escaping Local Control

To determine the change in the probability that an outbreak, caused by a laboratory accident, would escape local control and seed a global pandemic, refer to Section 6.6. This section demonstrates that of the modifications described in this example, only transmissibility is known to have a significant influence on the probability that an outbreak would escape local control. To determine HOW changes in this trait affect this probability, refer to Section 6.6.1 and Figure 6.29, specifically, for seasonal influenza strains. This figure shows that, should an outbreak resulting from an accident occur, this wild type strain (R_0=1.3) has a baseline chance of escaping local of roughly 21% (12-30% using 80% of the parameter values in the assessment). If the highly transmissible Strain 2 (R_0=1.7) were to cause a local outbreak, the probability that the outbreak would escape local control and seed a global pandemic increase to 44% (27-50%). Because, as described in Section 6.2.9 and Figure 6.12, the range of results in the figures reflect monotonic increases with the same overall shape as the median estimate, one can directly compare the median estimate and the extremes of the range given for any set of results. For this reason, this specific modification is estimated to increase the probability that an outbreak would escape local control by 2.1-fold (1.6-2.3x). If the transmissibility could be increased to rival the most transmissible pandemic influenza strains, the risk of local escape would be further increased.

Table 6.8. Summary of the Influence of Exemplar Modifications to Seasonal Influenza on the Probability That an Outbreak, Caused by a Laboratory Accident, Would Escape Local Control and Seed a Global Pandemic

Strain	1=wild type	2=highly transmissible	3=attenuated
Increase in probability of an outbreak escaping local control	1, defined	2.1x (1.6-2.3x)	1, no change due to modification

6.9.3 Step 3: Determine if the Consequences of a Resulting Pandemic Changes

To determine how the consequences of a global pandemic changes, refer to Section 6.7. Within Section 6.7 refer to the section describing each modified trait of interest to understand how changes in that trait affect this probability. This section demonstrates that both of the modifications described in this example affect the consequences of a global pandemic.

To determine how changes in transmissibility affect consequence, refer to Section 6.7.5.1 and Figure 6.44, specifically, for seasonal influenza strains. This figure shows that, should a global pandemic occur, this wild type strain (R_0=1.3) would lead to roughly 500,000 global deaths (150,000-4,000,000 using 80% of the parameter values in the assessment and assuming no community mitigation occurs). If the highly transmissible Strain 2 (R_0=1.8) were to cause a global pandemic, the deaths suffered would increase to 900,000 (250,000-10,000,000). Because, as described in Section 6.29 and Figure 6.12, the range of results shown in the figures reflect monotonic increases with the same overall shape as the median estimate, one can directly compare the median estimate and the high and low parts of the range given for any set of results. For this reason, this specific modification is estimated to increase the consequences of a global pandemic by 1.8-fold (1.6-2.5x).

To determine how modified pathogenicity affects global consequences should a global pandemic occur, refer to Section 6.7.6 and Figure 6.48, specifically for seasonal influenza. Although this figure visually

displays how case fatality rate affects global deaths, the change in deaths is simple to calculate as a tenfold decrease in the case fatality rate simply leads to a tenfold decrease in global deaths.

Table 6.9. Summary of the Influence of Exemplar Modifications to Seasonal Influenza on the Consequences of a Global Pandemic

Strain	1=wild type	2=highly transmissible	3=attenuated
Increase in global consequences	1, defined	1.8x (1.6-2.5x)	0.1

6.9.4 Putting it Together

Because the risk of a pandemic in this study is the product of the frequency of a laboratory incident sparking a local outbreak, the frequency of an outbreak escaping local control and the consequences of a global pandemic, the total change in risk can be simply understood as the product of the increases in any of these values over the baseline.

The highly transmissible Strain 2 is as likely to escape from a laboratory, but 2.1-fold (1.6-2.3x) more likely to cause a pandemic that would kill 1.8-fold (1.6-2.5x) more people than the wild type strain. In total then, research on this strain poses 3.8-fold (2.6-5.8x) more risk of pandemics than research on a wild type seasonal influenza strain. Put another way, GoF experiments that increase the transmissibility of seasonal influenza to the level of pandemic influenza strains are 3.8-fold more risky than alternate experiments involving wild type strains. In contrast, if the research could be conducted with an attenuated strain instead of a wild type strain, risk would decrease by a further tenfold.

7 Biosecurity Risk of Malicious Acts Targeting a GoF Laboratory

7.1 Biosecurity Risk Assessment: Summary

The purpose of the biosecurity risk assessment is to provide NSABB with an assessment of the likelihood that a malicious act involving a GoF influenza, SARS-CoV, or MERS-CoV virus could result in local infections or widespread pandemic. The risk assessment involved five steps: 1) characterization of the threat, which includes an evaluation of historical incidents and malicious actor motivation and capability (the "offense"); 2) review of the current security policies and practices landscape that governs research with influenza, SARS-CoV, and MERS-CoV in the United States (the "defense"); 3) identification of plausible threats based on analysis of the "offense" and "defense"; 4) assessment of the potential for the plausible threats to cause infections in the local community or broader; and 5) comparison of possible pandemic consequences of plausible threats involving GoF viruses and non-GoF viruses.

No unclassified information describing the threats to research laboratories that store or study GoF influenza, SARS-CoV, or MERS-CoV virus is available. Therefore, to identify the types of actors and acts that may target a GoF laboratory, our approach involved examining historical incidents involving life science laboratories and hospitals, evaluating the motivations and capabilities of malicious actors, and determining if and how existing security measures affect the likelihood of success of a malicious act. Plausible threats facing laboratories that study or store GoF virus(s) were extrapolated from this assessment. Figure 7.1 presents a schematic of the biosecurity risk assessment process.

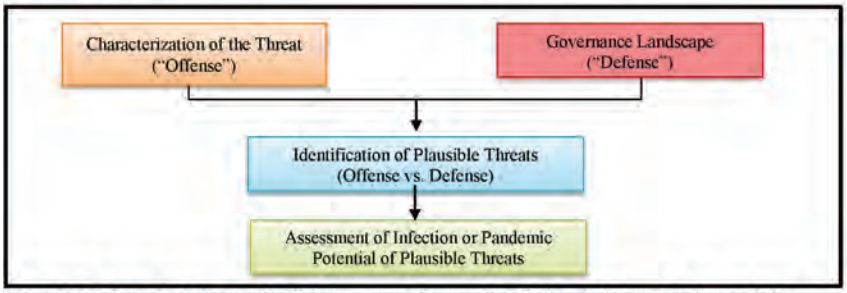

Figure 7.1. Schematic of Biosecurity Risk Assessment Process. Detailed methodology is in Appendix V, Section 16.2 and 16.3.

7.1.1 Malicious Actors and Acts

In today's regulatory and security environment, the main plausible threat facing high containment, research laboratories that store or study GoF viruses, involves malicious insiders who have authorized access to the laboratories and virus(s) contained therein. Insiders may work alone or in coordination with an outside group. Their motivations range from emotional disturbances to ideological radicalization by domestic and transnational terrorist organizations. The likelihood that outsiders could gain access to a laboratory without insider assistance is low. Therefore, outsiders present a threat to the periphery of the research complex or building only, but not a significant threat to the high containment laboratory itself.

7.1.2 Security Governance

Governance of infectious disease research is extremely complex, involving international agreements, domestic law, guidance, and contractual requirements in addition to institutional, local, and state-specific policies. Highly pathogenic avian influenza, the reconstructed 1918 influenza, and SARS-CoV viruses are

all Select Agents and are therefore covered by the Select Agent Regulations. Low pathogenic avian influenza and MERS-CoV are not Select Agents. Security systems, protocols, and practices at non-select agent, select agent, and Tier 1 select agent levels were reviewed to evaluate the likelihood of a malicious actor carrying out a successful act involving a laboratory that stores or studies a GoF virus. Analysis of plausible threats accounts for current security measures at the lowest level at which GoF research is conducted.

7.1.3 Qualitative Assessment: Plausible Threats

Based on historical incidents, the most likely malicious acts to be carried out in or on a laboratory that studies or stores GoF virus(s) include removal of the virus from frozen stocks, experimental samples, equipment, or research animals; deliberate contamination of personal protective equipment or laboratory equipment; deliberate compromise of the personal protective equipment or laboratory equipment; and mixing of infected with uninfected samples or animals outside proper containment. In addition, incidents involving bombs or active shooters may cause loss of containment if carried out inside or near the entrance of high containment laboratories in which GoF research is conducted. Noncompliance with security regulations and networked control systems might increase laboratory biosecurity risks. Table 7.1 summarizes these plausible threats, including both malicious actor and act.

Table 7.1. Plausible Threats Involving High Containment Research Laboratories That Store or Study GoF Viruses

Overt	Insider	Active shooter or physical assault Bomb detonated near or inside high containment space
	Outsider	Bomb detonated at building periphery
Covert Act (Expose Public)	Insider	Removal of GoF virus (frozen stock or experimental sample), infected animals, or contaminated equipment
Covert Act (Expose Laboratory Workers)	Insider	Removal of GoF virus in experimental samples Deliberate contamination of personal protective equipment or laboratory equipment Deliberate compromise of laboratory equipment or personal protective equipment Mixing of experimental samples or animals into lower containment

7.1.4 Conclusions

The existing regulatory infrastructure governing influenza, SARS-CoV, and MERS-CoV appears to provide sufficient defenses, if properly implemented, against unauthorized outsiders from accessing modified viruses. However, clarity and guidance associated with current policies could be improved to enhance compliance with required security measures. In addition, data that could be used to inform the need for additional security measures does not exist (or is not in the public domain).

Only a handful of GoF traits significantly increase biosecurity risk after a malicious event targets a laboratory. For seasonal and pandemic influenza, the ability to overcome protective vaccination and antiviral resistance modestly increases risk by increasing the potential consequences in the high income countries. There is no significant effect on risk if the global population is considered as a whole. Increasing the transmissibility and ability to evade residual immunity significantly exacerbates risk because outbreaks are more likely to occur, to escape local control and will create more consequential global outbreaks. For avian influenza, increasing transmissibility greatly increases risk because this

modification is required to spark a global outbreak of a disease by human-to-human contact, potentially infecting millions. Without this change, the hazard is restricted to those exposed to contaminated materials and infected birds, limiting the outbreak to thousands of cases at most. Increasing pathogenicity can modestly increase risk. Similarly, the wild type coronaviruses have a very small chance of sparking a global outbreak so increasing transmissibility greatly increases risk. Increasing pathogenicity can modestly increase risk.

When comparing the biosafety and biosecurity risks, a successful event that covertly infects the public (theft from an influenza laboratory of an infected animal, contaminated piece of equipment or viral stock) must occur once every 65-190 years for biosecurity event to have the same total risk as biosafety events. Given the frequency with which these malicious acts have occurred in the past, this analysis suggests that biosecurity considerations be given as much weight as biosafety issues.

7.2 Findings: Assessment of the Offense (Possible Threats to US Research Laboratories)

Incidents of criminal, terrorist, and illicit governmental activities involving pathogens, US laboratories, and/or researchers have been documented in several books, articles, official government documents, and other open source publications. However, the potential risks of intentional or accidental release of laboratory-generated or adapted pathogens into the community or environment from deliberate acts whose main goal is not bioterrorism often are not included in these accounts. Similarly, the risk that cyber breaches may result in the intentional disruption of facility operations has not been fully described in open literature. The lack of publicly available data about the likelihood that a cybersecurity breach could disrupt facility operations and control systems of high containment laboratories makes assessing such threats prohibitively difficult in unclassified settings. Therefore, the potential threats to human health that cyber breaches pose are not addressed in this report.

In our assessment of the potential biosecurity threat associated with GoF influenza, SARS-CoV, and MERS-CoV research, a variety of malicious actors, malicious acts, and consequences, including deliberate incidents that resulted in accidental release and cyber security breaches were evaluated. Furthermore, the motivations and capabilities of each malicious actor type based on conventional knowledge and historical events found in open source documents were evaluated. Finally, historical incidents of deliberate harm or application of science for destructive purposes were considered in this analysis.

The following section summarizes actual malicious acts against laboratories and health care facilities, or involving attempts to acquire pathogens based on analysis of the open-source, historical literature. Figures 7.2 – 7.4 summarize all of the historical events that occurred in the United States over the past 25 years based on open source reporting.

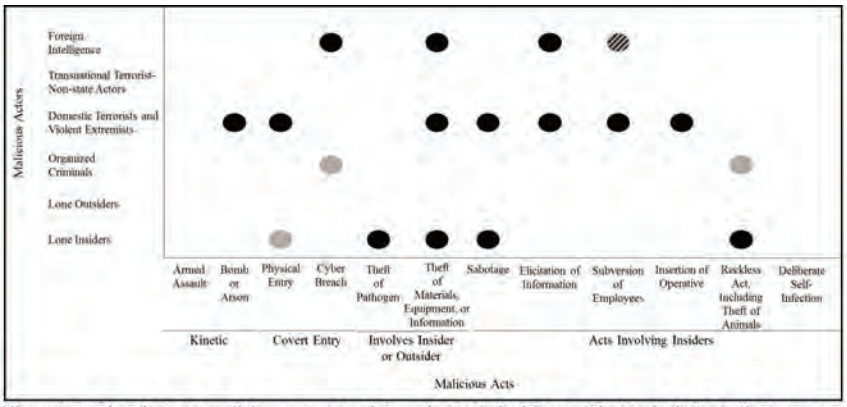

Figure 7.2. Historical acts malicious actors carried out in the United States. The black circles indicate two or more historical events, the grey circles indicate one historical event, and the cross-hatched black-grey circles indicate one or two historical events.

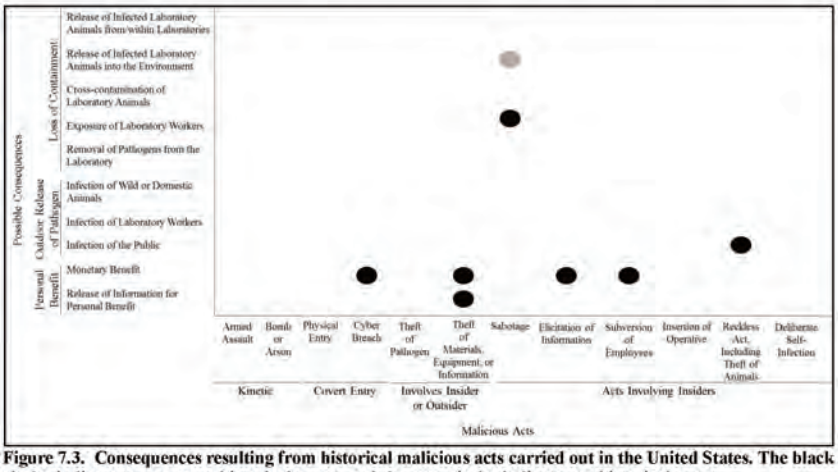

Figure 7.3. Consequences resulting from historical malicious acts carried out in the United States. The black circles indicate two or more historical events and the grey circles indicate one historical event.

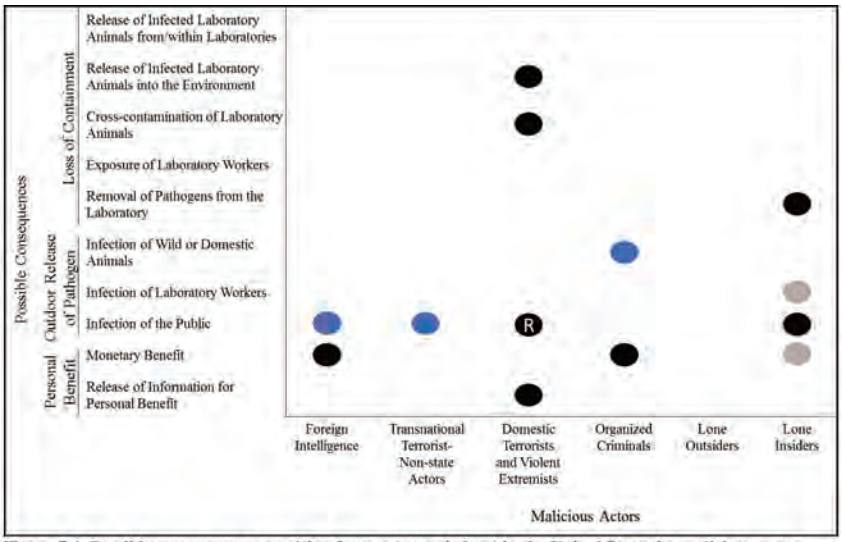

Figure 7.4. Possible consequences resulting from acts carried out in the United States by malicious actors. The black circles indicate two or more historical events, the grey circles indicate one historical event, the grey hatched circles indicate group efforts that may/may not have been associated with a criminal organization, and the blue circles indicate hopeful outcomes of planned or attempted (but failed) events. The "R" in one of the black bubbles indicates the Rajneeshee Cult, who are the only group of domestic terrorists that deliberately exposed members of the public.

7.2.1 Malicious Actors

The following key findings are reached regarding malicious actors, based on the research presented in the section above:

- Analysis of past acts by malicious actors that involved a US laboratory shows that, out of a universe of possible acts, relatively few malicious acts with the potential to lead to a breach in containment have been carried out.

- The majority of the documented prior acts have been committed by domestic terrorist and extremist groups, specifically by animal rights extremists. These groups have engaged in a wide range of malicious acts, including laboratory arson, sabotage, subversion of employees, and reckless acts such as the release of laboratory animals. Although these actions probably did not seek the release of a pathogen from a laboratory, they nevertheless have resulted in such an outcome on at least one occasion. In one case dating from 1989, animal rights extremists released 30 infected mice infected with cryptosporidium from a laboratory, probably without knowing that the mice were infected.[367] However, animal rights extremists have been rigorously pursued and

[367] "Diseased mice freed in arson fires, break-in," *Spartanburg Herald-Journal*, April 4, 1989, A2. Retrieved at: https://news.google.com/newspapers?nid=1876&dat=19890404&id=2kwsAAAAIBAJ&sjid=Vs4EAAAAIBAJ&pg=6664,1859692&hl=en.

arrested by FBI in recent years.[368,369,370,371] The number of animal rights attacks appears to have decreased in recent years because of increased security at research institutions[372] and increased arrests by law enforcement.

- Many documented events occurred before new counter-terrorism and counter-extremist laws and policies were put into place. With these new requirements in place, carrying out a malicious act today against a high containment laboratory in the United States is challenging, which might deter or prevent groups from repeating past attacks. This idea was highlighted in propaganda from one animal rights extremist group, which blamed their decreased activity against laboratories on the difficulty of penetrating "increased security."[373]

- Insiders pose a significant risk because of lone actor incidents, the unpredictability of emotionally disturbed insiders, potential for radicalization by extremists or terrorists, or elicitation or subversion incidents. Insiders have carried out or been involved in malicious acts involving the diversion of a pathogen from a laboratory and the infection of someone in the general public. In addition, noncompliance with security regulations increases the potential biosecurity risk posed by insiders.

- Transnational terrorist groups, including state-like groups, were found to be unlikely to target US laboratories directly through armed assaults or bombings. However, foreign terrorist organizations, such as al Qaeda and ISIL, have issued calls for scientists, doctors, and engineers to join their cause, which includes the use of specialized skills to inflict harm.

- Foreign intelligence entities have and continue to target biological laboratories to steal information or laboratory materials. These efforts can be done through elicitation or subversion of laboratory employees, insertion of an operative, or more recently, remotely through hacking into institutional computer networks. No information in open source literature links these incidents of theft to release of a biological agent.

- In the past, a select few foreign intelligence agencies weaponized biological agents for use in assassinations. In addition, the Soviet Union's KGB targeted Western research on modified pathogen strains, possibly to bolster the Soviet offensive program.[374]

373 Ibid.

374 Leitenberg M., Zilinskas R., (2012) *The Soviet Biological Weapons Program: A History*. Cambridge, MA, Harvard University Press

- Organized criminals have not attempted to steal pathogens from a US laboratory. However, one case of cyber-crime suggests that theft of information on applied life science research can be lucrative, and therefore tempting, for organized criminal groups.

- Lone outsiders do not pose a significant threat to research laboratories, especially Biological Select Agent and Toxin laboratories, because they do not have access to the facilities. By definition, these actors are not working with an insider and would not have opportunities to gain access to facilities in the absence of intentional or unintentional assistance[375] of an insider.

Interviews confirmed the following threats of concern:

- **Insiders** with access to information and pathogens and who become discontented or disgruntled, radicalized, or elicited or subverted are a security concern.

- **Transnational terrorists** who are interested in biological weapons are a security concern.

- **Domestic extremists**, such as animal rights extremists, anti-vaccine extremists, and eco-radical groups, who see harming researchers and institutional administrators, and/or vandalizing institutional facilities as a useful approach to convey their messages are a security concern The threat posed by domestic extremists appears to vary by the laboratory's location.

- **Lone outsiders** do not raise much concern because they are not working with an insider and have difficulty accessing laboratories and breaching facility defenses unassisted.

- **Active shooters** on university campuses are of significant concern even though **no** incidents involving an active shooter in a high containment laboratory have been described.

7.2.2 Malicious Acts

The following key findings are reached regarding malicious acts, based on the research presented in the section above:

- Armed assaults at laboratories have not occurred previously, but with increasing incidents of active shooter cases on university campuses, the potential for armed assault might exist.

- A bombing attack against a US lab has not taken place. Because malicous actors have bombed hospials and related facilities, this type of attack remains possible.

- No exposure or release events have occurred from sabotage, despite the relative frequency of sabotage incidents.

- Reckless acts provide the greatest opportunity for an outbreak to occur, and have occurred on several occasions in the past, as documented above.

- A deliberate infection of a member of the public through a deliberate or reckless act by an insider represented the most common pathway for loss of containment across the spectrum of malicious actors and acts considered.

[375] An example of unintentional assistance by an insider is access through an insider not complying with physical, information, or transportation security measures.

- A reckless act involving the release of an infected animal outside of containment has occurred once before, as a result of an attack by a domestic animal rights extremist group who likely did not know the mice were infected.

- Deliberate self-infection remains a hypothetical concern. The closest event documented in open source literature is one reported HIV self-infection case involving an outsider without lab access who attempted suicide, probably with the help of an infected friend.[376]

- Interviews confirmed cyber breach of computer networks and cyber security issues are a significant concern particularly because they have resulted in several incidents of information theft. Furthermore in the early 2000s, a computer worm infected the software of an Iranian uranium enrichment plant, in addition to other industrial sites, affecting operations of Iranian nuclear centrifuges.[377,378] The Department of Defense (DOD)'s Defense Science Board Task Force considered the potential threat of cyber-sabotage in their May 2009 assessment of DoD laboratory security, and recommended that an in-depth study be conducted to determine the potential cyber threat against US laboratories.[379]

A summary of the findings drawn from open source literature is presented in Figure 7.5 which highlights combinations of malicious actors, acts, and consequences of malicious acts based on historical incidents (in green, red, and red/green circles) and identifies possible combinations based on an evaluation of malicious actor motivation and capability (blue, blue hatched, or blue diagonal circles). This summary of findings will be described in detail in the following sections.

Possible threats based on historical events (green, red and green-red cross-hatched circles) and malicious actor motivations and capabilities (blue solid, cross-hatched, and patched circles). The green circles indicate two or more historical events, the red circles indicate one historical event, and the cross-hatched green-red circles indicate one or two historical events. The blue circles indicate possible threats based on malicious actor motivation and capability. The patched blue circles indicate planned or failed attempts. The cross-hatched blue circles indicate limited possibility.

7.2.3 Detailed Descriptions

Detailed descriptions of malicious acts perpetrated by various malicious actors (lone outsider, lone insider, organized criminals, domestic terrorists and violent extremists, transnational terrorist non-state groups, and foreign intelligence entities) are included in Appendix V to this report:

Section 16.4: Analysis of Malicious Actor Motivations and Capabilities
Section 16.5: Detailed Analysis of Historical Incidents
Section 16.6: Attacks Against Laboratories
Section 16.7: Biocrimes Committed by Individuals
Section 16.8: Terrorist and Extremist Events Tied to Biological Warfare (BW)
Section 16.9: Designated Foreign Terrorist Organizations and BW
Section 16.10: Detailed History of Known Terrorist BW Programs
Section 16.11: Other Terrorist Groups Linked in Some Fashion to BW
Section 16.12: Islamic State in Iraq and the Levant (ISIL) Group Overview

Some types of successful incidents may go undetected, and in general, incidents may be tied to sensitive law enforcement and intelligence information. Hence, open source reporting alone is unlikely to lead to a complete list of all relevant historical incidents. Historical patterns can be disrupted, for instance, as a result of the widespread implementation of new security programs, by the arrest of key group members, and by the emergence of new malicious actors. Malicious actors may decide, in line with shifts in motives and capabilities, to change the way they operate and to select new targets. To address the potential shortcomings of relying solely on historical data, hypothetical events are also considered in light of the motivations and capabilities of each malicious actor type. That is, when no historical case has been identified for a particular actor-act pairing, an argument is presented to explain why that pairing is unrealistic or, on the contrary, for why it cannot be discounted. These cases are called hypothetical.

7.3 Findings: Defense Assessment

An assessment of the overall risk posed by malicious actors necessitates an evaluation of the current governance structure for biosecurity and related policies and the implementation of security measures at research institutions. The historical and operational links between safety and security highlight the need to include both in this evaluation.[380] In addition, the agents associated with the Deliberative Process – influenza, SARS-CoV, and MERS-CoV – are subject to different requirements. Highly pathogenic avian influenza and SARS-CoV are select agents subject to the Biological Select Agents and Toxins Regulations.[381] Although no GoF viruses are currently Tier 1 BSAT, a recent Notice of Proposed Rule-Making has asked for public input on the upgrade of laboratory-generated, mammalian-transmissible H5 influenza viruses (specifically, those viruses that are contain the HA from the A/Gs/Gd/1/96 lineage and made transmissible among mammals by respiratory droplets in the laboratory) to the Tier 1 level of Biological Select Agents and Toxins.[382] Low pathogenic influenza and MERS-CoV are not classified as Biological Select Agents and Toxins. For this reason, included in this analysis are security measures, whether from governing documents and practices on safety or security, at the non-select agent, select agent, and Tier 1 select agent levels.

7.3.1 Overview of Security Measures

Table 7.2 below summarizes specific requirements applicable for all laboratories depending on their biosafety level (second column), additional requirements enforced at laboratories working with Select Agents and Toxins (third column), and additional requirements enforced at laboratories working with Tier 1 Select Agents (fourth column). The second column constitutes the base level of security, and each column thereafter lists additional security requirements. The September 2014 institutional DURC oversight policy applies to select agent and Tier 1 select agent laboratories and to non-select agent laboratories conducting research with *di minimus* quantities of botulinum toxin.

Table 7.2. Security-Specific Requirements in General, Select Agent, and Tier 1 Select Agent Labs

Topic	General	Select Agent (in addition to General)	Tier 1 Select Agent (in addition to Select Agent)
Personnel Training	• Appropriate biosafety training • Dual use research of concern training (for research involving *di minimus* quantities of botulinum toxin that is considered to be DURC)	• Security training, at least annually • Dual use research of concern training (for research assessed as DURC)	• Insider threat awareness training • Stricter personnel reliability reporting
Personnel Reliability	• DoC and/or DoS permits for pathogen access by foreign nationals (if needed)[1] (Reference checks for new hires; optional)	• Individual security risk assessment • Suspicious activity reporting process • Separate criminal background check (optional) • DoC and/or DoS permits for pathogen access by foreign nationals (if needed)[1]	• Pre-access suitability assessment • Formal continuous suitability assessment (Behavioral threat assessment teams optional)
Physical Security	• Self-closing lockable doors (BSL-2 and up, all animal) Separate space from traffic flow, doors locked (BSL-3 and up, all animal) • Separate building or zone, locked doors (BSL-4, ABSL-4) • Self-closing doors (animal) • Sealed (BSL-3 and up) and break-resistant (BSL-4) windows • (Windows not recommended for ABSL vivarium; optional) (ID badges, access control, "normal" working hours; optional) (Electronic cardkey access; optional)	• Physical security in security plan • Procedures to remove potential malicious actors • Reporting potential crimes or access control issues • Access control management • Inspection of suspicious packages • Escort visitors	• Three security barriers, one monitored • Access control on final barrier • Backup power for access control systems • Response time at or under 15 minutes, or physical barriers adequate to hold until responders arrive Restricted off-hours access even for approved staff • Procedures for visitors, their property, and their vehicles

Table 7.2. Security-Specific Requirements in General, Select Agent, and Tier 1 Select Agent Labs

Topic	General	Select Agent (in addition to General)	Tier 1 Select Agent (in addition to Select Agent)
Surveillance and Monitoring	• Access controls and training requirements • Alarmed exits (BSL-4, ABSL-4) • Occupational health monitoring (BSL-4, ABSL-4, lower levels by risk assessment • Ventilation alarms (BSL-3 and up, optional below level 4) • Facility video surveillance (optional, generally not monitored) • Yearly facilities inspection – biosafety cabinets, HVAC	• No additional requirements	• Intrusion detection systems • Occupational health monitoring
Storage, Inventory, and Accountability Processes	• General inventory and material management process for biological stocks (optional) • Record entry/exit in logbooks (BSL-4, ABSL-4)	• Record number of containers, storage location, and chain-of-custody information for long-term storage • Record animal counts, species, location, and final disposition • Access records in logbooks • Access control to inventories • Inventory audits after moving, PI turnover, or theft/loss • DoC and/or DoS permits for pathogen export[1]	• More stringent reviews, logs, and inventory audits (optional)
Transfer, Shipment, and Chain-of-Custody Protocols	• Triple package agents[2] o Labeling requirements for air shipment[2] o Import permit • (CDC, USDA), interstate permit (USDA), potential need for interstate transfer permits for imported samples (CDC, case-by-case) [2] • DoC and/or DoS permits for pathogen export (if needed) [1]	• Shipping permits from CDC/APHIS required[2] o Report receipt or loss/theft/delay to CDC/APHIS within 48 hours[2] o Report damage to CDC/APHIS immediately[2] • Record transfers • DoC and/or DoS permits for pathogen export[1]	• No additional requirements

Table 7.2. Security-Specific Requirements in General, Select Agent, and Tier 1 Select Agent Labs

Topic	General	Select Agent (in addition to General)	Tier 1 Select Agent (in addition to Select Agent)
Emergency Response Protocols	• External communication capability (BSL-4, ABSL-4) • Emergency access and egress plans (BSL-4, ABSL-4) • Plans for man-made or natural disasters (Animal)	• Annual drills to test emergency and incident response plans	• Security response time at or below 15 minutes, or physical barriers adequate to hold until responders arrive

7.3.2 Detailed Descriptions

A detailed analysis of the requirements, implementation practices, and current gaps in security measures is provided in Appendix V of this report.

Section 16.13: Biosafety and Biosecurity at US Research Laboratories
Section 16.14: Laws, Guidance, Policies, Practices, and International Agreements on Biosafety and Biosecurity
Section 16.15: Restriction of Fundamental Research, Dual Use Research of Concern, and NIH Guidelines for Recombinant DNA
Section 16.16: Analysis of Security Measures
Section 16.17: Major Challenges and Knowledge Gaps

7.4 Analysis of Offense and Defensive Measures

The biosecurity risk assessment presents a semi-quantitative evaluation about whether deliberate acts involving GoF influenza, SARS-CoV, or MERS-CoV will result in a local outbreak or pandemic. The assessment involves: 1) qualitative analysis of plausible threats facing institutions that conduct GoF influenza virus, SARS-CoV, or MERS-CoV research based on systematic evaluation of historical

incidents, malicious actor motivations and capabilities, and implemented security measures at US research institutions and 2) quantitative analysis of the potential for the plausible threats to cause infections in the local community or broader and of the comparison of possible pandemic consequences of plausible threats involving GoF influenza virus, SARS-CoV, or MERS-CoV and non-GoF viruses. Although an actual or attempted biosecurity incident could cause significant damage to research progress, national preparedness and response efforts, the nation˜s economy, or socio-political situation, the assessment focuses on the consequences to human health (both illness and death) at the individual (i.e., laboratory worker, malicious actor, or emergency personnel) and population (i.e., local or global communities) levels should a pathogen be removed from containment deliberately or accidently.

No unclassified information describing the threats to research laboratories that store or study GoF influenza, SARS, or MERS-CoV virus is available. Therefore, to identify the types of acts that may target a GoF laboratory, our approach involved examining historical incidents involving life science laboratories and hospitals, evaluating the motivations and capabilities of malicious actors, and determining if and how existing security measures affect the likelihood of success of a given malicious act. All of the data collected on potential threats and biological security governance were used to assess the plausible threats facing laboratories that study or store GoF virus(s).[382] For the purpose of this analysis, "plausible threats" are defined as the most probable events that could lead to a loss of containment from a biosecurity incident. Therefore, the analysis focused on the plausible threats assessed within the current context of laboratory security and their potential to lead to localized or widespread infections.

The malicious acts that present the greatest risk to human health are assessed sequentially, starting with malicious actors. The most plausible actors are further evaluated by the most probable and consistent malicious acts they may commit. Finally, the most likely immediate consequence of a probable and consistent act that has been committed is evaluated. At each step, probable threats are evaluated within the context of current security measures at US high containment research laboratories. The final result is the most plausible threats based on evaluation of historical data, consistency with malicious actor motivation and capability, and likelihood within the current security environment at high containment research laboratories in the United States.

The potential of plausible malicious acts to cause global pandemic was assessed using the biosafety risk assessment models. By leveraging the biosafety risk assessments to analyze biosecurity risk, the important input parameters become the number of initial infections and response time after an incident (including emergency response and/or public health response). Deliberate and accidental risks result in vary similar outcomes and this approach allows for comparisons to be made between biosafety and biosecurity risks that cause similar human health outcomes.

7.4.1 Qualitative Assessment of Plausible Threats

7.4.1.1 Malicious Actor

Analysis of malicious actor intent falls into two categories: 1) intent to target US research institutions to acquire GoF viruses for use as weapons; and 2) intent to harm US research institutions and/or laboratory workers, but not through the weaponization of pathogens stored or studied in research laboratories. Table 7.3 summarizes the likelihood that the malicious actors considered have the intent, capability and ability to access laboratories with respect to each of these categories. The analysis is based on an evaluation of historical cases and malicious actor motivations and capabilities described in Section 7.4 and Appendix V

[382] Noncompliance with security regulations might increase biosecurity risk intentionally or unintentionally. However, because no repository of tested best practices exist, some requirements may not be easily implemented at research institutions given building design, institutional policies, and local and state laws.

Section 16.2-16.9 and the safety and security measures included in Section 7.5 and Appendix V Section 16.10-16.11. Although this assessment is grounded in historical incidents, incorporation of malicious actor motivations and capabilities ensured that plausible incidents that have not previously occurred would be considered. Of greatest relevance to the discussion about actors is their definition: outsiders are not authorized to access high containment research laboratories in which GoF research with influenza, SARS-CoV, or MERS-CoV are conducted, while insiders are authorized to access such laboratories by definition. The approach taken in this analysis can be applied to biosecurity risk assessments of research involving other pathogens.

Table 7.3. Malicious Actor Intent, Capability, and Opportunity

	Deliberate Acts that Use of Pathogens as Weapons			Deliberate Act Resulting in Accidental Release of Viruses		
	Intent to Acquire Virus to Use	**Capability to Acquire Virus**	**Ability to Access Laboratory**	**Intent to Carry Out Malicious Act**	**Capability to Carry Out Malicious Act**	**Ability to Access Laboratory**
Foreign Intelligence Agencies						
Transnational Terrorists, non-state actors						
Domestic Terrorists and Extremists						
Organized Criminals						
Lone Outsiders						Only to outside of building
Lone Insiders						

Black *indicates consistency of intent, capable, or able to access high containment, research laboratories with known malicious actor motivations and capabilities, and historical incidents.*

Dark ***Grey*** *indicates possible intent, capable, or able to access high containment, research laboratories with known malicious actor motivations and capabilities, and historical incidents.*

Grey *indicates inconsistency of intent, capable, or able to access high containment, research laboratories with known malicious actor motivations and capabilities, and historical incidents.*

7.4.1.1.1 Deliberate Act at US Research Laboratory to Use Pathogen as Weapon

The most likely actors with **intent** to target US research institutions to acquire GoF influenza virus, SARS-CoV, or MERS-CoV for use as weapons are transnational terrorists and lone insiders.

- Although foreign intelligence agencies may want to acquire viruses, their purpose for doing so is likely for intelligence, scientific advancement in their home countries, or commercial benefit.

Although the possibility that foreign intelligence agencies may want to acquire GoF virus to incorporate into their offensive biological weapons cannot be ruled out, the likelihood of this intent is low. Approximately 172 countries are party to the Biological Weapons Convention, which bans development and stockpiling of biological weapons, and all nations are required to abide by United National Security Council Resolution 1540, which requires countries to implement and enforce measures preventing proliferation of biological weapons within their borders. These international obligations decrease (but does not eliminate) the likelihood that Nations acquiring a virus for an offensive biological weapons program.

- Translational terrorists, specifically al Qaeda, continue to express interest in acquiring pathogens for use as weapons. In addition, al Qaeda and ISIL have recruiting efforts that target individuals with technical skillsets to join their causes and undertake malicious acts within their means. However, no available information suggests that these groups have recruited scientists in the US or that other transnational terrorist groups have interest in biological weapons. For these reasons, the intent of transnational terrorists is described as possible.

- In our analysis, individuals who self-radicalize and plan to or carry out a malicious act in the absence of a formal affiliation with a terrorist organization are considered Lone Outsiders or Lone Insiders. This distinction is made because the level of resources, support, and success afforded a member of a group compared to an individual acting alone is different, all of which will be described in the analysis of capabilities, access, and likelihood of malicious acts.

- Historically, members of domestic terrorist groups, but not animal rights extremist or eco-radical groups, have sought to acquire bacteria from culture collections. Similarly, recent policy debates about synthetic genomics have raised concerns that individuals, some of whom may be members of these groups, may seek to acquire viral DNA from DNA synthesis companies to recreate viruses. However, no available examples exist describing cases where domestic terrorist groups have sought to steal or have successfully stolen viruses from high containment laboratories in the United States, suggesting the intent to do so is inconsistent with their motivations. However, one example exists describing a domestic terrorist group that used an agent against the public to sway a local election (Rajneeshee Cult).

- Organized criminals and lone outsiders are not likely to be interested in stealing virus from a high containment laboratory based on the lack of open source examples of such incidents and our understanding of the motivations of organized criminals.[384]

- Several historical cases involving lone insider theft and use of bacteria to harm others were identified in open source literature during our study. These cases have involved disgruntled, dissatisfied, disturbed, or radicalized insiders who remove a pathogen from a laboratory to infect co-workers, spouses, or family members. Extrapolating these cases to GoF viruses, the possibility that a lone insider, with malicious intent, may acquire virus from a research laboratory to use as a weapon is high.

When divorcing intent from capability, the most likely malicious actors to have the **capability** to acquire GoF influenza virus, SARS-CoV, or MERS-CoV from US research laboratories are foreign intelligence entities, an insider acting alone or in concert with any category of malicious actors, and lone insiders.

[384] Historical examples of lone outsiders acquiring bacteria from culture collections do exist. But, to our knowledge, culture collections do not have GoF influenza, SARS-CoV, or MERS-CoV viruses.

- Many foreign intelligence agencies have the resources and levels of expertise to suggest they have a high level of capability. In addition, these agencies are known to elicit information from insiders as part of their typical tradecraft.

- Transnational terrorists, domestic terrorists, and domestic extremists themselves are unlikely to have the requisite capability to illicitly acquire a virus from a high containment laboratory in the United States. However, documented historical cases describing insider recruitment suggest that insider-assisted capability is likely.

- Organized criminals and lone outsiders are unlikely to have the capability to steal virus from a high containment laboratory, particularly since no open source examples exist. However despite the lack of motivation, the possibility that organized criminal groups force insiders to assist in acquiring virus cannot be ruled out.

- Lone insiders present the highest risk when considering capability because they have the knowledge, skills, and access necessary to acquire and/or manipulate the viruses.

When considering an actor's **ability to access** a GoF influenza virus, SARS-CoV, or MERS-CoV in a high containment research laboratory in the United States, the most likely malicious actors to have access are foreign intelligence entities, an insider acting alone or in concert with any category of malicious actors, and lone insiders.

- Research institutions supporting animal research and high containment research have access controls in place to protect against unauthorized access to the laboratories. These controls can take the form of guards; electronic, biometric, or mechanical intrusion prevention/detection systems; and/or some combination of these measures. Based on these access controls, along with periodic monitoring of access to laboratories, the likelihood that any outsider, who is not working with an insider, could gain access to the high containment, research laboratory to acquire GoF virus is extremely low. That said, these security measures are only as good as the community who observe them (i.e., noncompliance with security regulations might increase insider-assisted biosecurity risks).

- Foreign intelligence agencies are known to elicit information and materials from insiders as part of their typical tradecraft, suggesting the possibility of gaining access to GoF viruses through indirect means. In addition, these agencies may have personnel who are authorized entrance into the laboratories and have direct access to GoF viruses (e.g., operative or elicited individual). Professionals likely would not be identified by currently implemented personnel reliability measures at research institutions or deterred by access control measures.

- Acting alone, translational terrorists are not likely to have any opportunities to acquire virus in high containment research laboratories in the United States. However, these organizations are known to recruit individuals to their causes, suggesting that they could acquire virus with the help of an insider (e.g., through elicitation, subversion, or recruitment). Current insider threat training and personnel reliability measures that allow for periodic behavioral assessment, specifically implemented for Tier 1 BSAT, and non-punitive reporting of changes in co-worker behavior (any level of research) could alert institutional officials to possible insider radicalization. However, colleagues may not recognize such changes or may be in denial that such changes are taking place in a friend or colleague, limiting the effectiveness of personnel security measures.

- Domestic terrorists, domestic extremists, organized criminals, and lone outsiders are not likely to have access to virus stored in high containment, research laboratories in the United States. Despite the lack of access, the possibility that domestic terrorists, domestic extremists, and organized criminals could acquire a virus with the help of an insider cannot be ruled out. Historical examples of domestic extremist groups gaining access to lower containment laboratories and eliciting information about facilities or attempting to get into animal facilities exist. However, the likelihood that such elicitation and access attempts would translate to acquisition of GoF virus is low in light of current access controls for high containment research laboratories, particularly BSAT laboratories, and personnel reliability measures for Tier 1 BSAT laboratories. Increased insider vigilance and non-punitive reporting would further decrease the likelihood of insider-assisted acquisition.

- Lone insiders are extremely likely to have opportunities to acquire virus from high containment research laboratories because they have authorized access to these laboratories. The monthly inventory checks on stored pathogens would not necessarily deter insiders (both lone insiders and insiders assisting groups) from removing virus from the laboratory. In addition, the identification of missing virus may be impossible if some virus is removed from a vial that remains in the freezer. In addition, inventory checks would not identify removal of virus from experimental samples.

- The possibility that an actor could steal pathogen during transportation appears to be low because GoF viruses apparently are not shipped.[385] Even if a virus was shipped, specific information about shipping dates, trucks, and vendors are not accessible to outsiders.

When evaluating intent, capability, and opportunity together, the most likely malicious actor to target a US research laboratory to acquire a pathogen for use as a weapon is an insider, either working alone or in coordination with a group, likely a transnational terrorist group.[386]

7.4.1.1.2 Deliberate Act at US Research Laboratory Resulting in Accidental Release of Viruses

Deliberate acts directed towards institutions and people, but not conducted for explicit acquisition of virus for use as a weapon, could target: 1) the research laboratory in which GoF research with influenza virus, SARS-CoV, or MERS-CoV is being conducted; 2) space outside the laboratory but inside the building which houses the laboratory; or 3) the area outside the facility in which the laboratory is housed. Such targeting could cause accidental release of virus from the laboratory. Specific acts associated with such targets could include armed assault, arson, bombing, vandalism and sabotage of facilities, tampering with experiments, and theft of materials, equipment, and animals.

The most likely malicious actors with the **intent** to carry out such acts include domestic terrorists and extremist groups, and lone insiders.

- The possibility that a foreign intelligence agency would carry about a deliberate act on a US research laboratory is low, especially since an attack could be construed as an act of war. This is particularly true for overt attacks, such as bombing, armed assault, or vandalism. However, the possibility that a foreign intelligence agency could accidently release a GoF virus through theft of materials or equipment cannot be ruled out.

---

[385] Scientists use reverse genetics to make GoF viruses instead of shipping them according to the scientists who were interviewed.

[386] An insider also is the most likely actor to acquire a virus for non-weapons purposes, such as personal or monetary benefit or assisting foreign intelligence agencies.

- No open source information exists indicating an intent by transnational terrorists to carry out a deliberate, malicious act on high containment research laboratories in the United States. However, the possibility that transnational terrorists may want to bomb a building cannot be ruled out because of the high prevalence of such tactics by several of these groups.

- No open source information exists indicating an intent by organized criminal groups to carry out a malicious act on or in high containment research laboratories in the United States. Organized criminals are driven by financial gain suggesting that the possibility that a criminal organization might seek to sell laboratory equipment for profit cannot be ruled out. However, the relative availability of common life science equipment for online purchase decreases the likelihood that an organized criminal organization will steal from a high containment laboratory in the United States.

- Several historical cases involve deliberate acts caused by domestic terrorists and extremists who have vandalized buildings, tampered with experiments in lower containment laboratories, released research animals into the wild or their own homes, or detonated bombs near buildings. The frequency with which these groups attack research institutions for ideological purposes indicates a high likelihood that they could carry out more such deliberate acts. However, additional security measures put in place under various regulations make such acts much more difficult to plan and carry out.

- Historical cases involving the use of bombs or armed assault in public areas and at hospitals by lone outsiders exist in open source literature. However, no open source information was identified about the targeting of US research laboratories by lone outsiders. Despite the lack of motivation, the possibility that a lone outsider would detonate a bomb or carry out an armed assault outside or in a research building cannot be ruled out. However, the motivation for such an attack is not clear.

- Historical examples of lone insiders tampering with experiments for personnel benefit or theft of virus for commercial benefit suggest the presence of clear motivations for lone insiders to carry out deliberate acts, some of which could result in accidental release of virus. Consequently, the likelihood of such acts is high.

When considering only **capability**, the most likely malicious actors to carry out deliberate acts that might result in accidental release of virus are foreign intelligence agencies, transnational terrorists, domestic terrorists and extremists, and lone insiders.

- Foreign intelligence agencies are expected to have the resources, tools, and expertise needed to carry out deliberate acts that could result in accidental release of GoF virus. In addition, these agencies are known to elicit information and materials from insiders as part of their typical work.

- No open source information about transnational terrorists targeting US research laboratories exists. However, the 2001 attacks and the violence carried out by individuals who may have been radicalized by transnational terrorists suggests their capability to carry out armed assault, arson, and bombing within the United States. Whether surveillance and monitoring of building perimeters would deter or prevent a transnational terrorist or sympathizer from carrying out an attack using these tactics is unclear.

- Domestic terrorist and extremist groups have bombed hospitals, released animals from research laboratories, vandalized research laboratories and equipment, and tampered with experiments.

Their proven ability to damage the building exteriors, damage low containment laboratories, steal animals, and tamper with experiments suggests they are capable of damaging buildings in which GoF research is being conducted. However, domestic terrorist and extremist groups are not likely to carry out deliberate acts inside a high containment research laboratory without the assistance of an insider with access. Increased security, including surveillance and monitoring of building perimeters and animal facilities, and increased arrests has decreased deliberate, violent acts involving animal rights extremists. Whether this extrapolates to other domestic terrorist or extremist group is unclear.

- No open source information exists about the capability of organized criminals to damage biological research facilities in the United States deliberately. Despite this unknown capability, organized criminals could use armed assault to gain access to the facility, but the exact purpose of doing so is unclear.

- Lone outsiders have detonated bombs in public areas and at certain clinics suggesting their potential capability to damage buildings in which GoF research is being conducted. Surveillance of building perimeters may deter lone outsiders from carrying out such acts. However, the increasing number of active shooter incidents at US facilities and educational institutions suggests that such actors are not deterred by surveillance and other similar measures.

- Lone insiders are expected to have the knowledge and skills to deliberately compromise or tamper with equipment and experiments. Furthermore, historical cases involving lone insiders who tamper with co-workers' experiments are described in open source literature. These cases and the presumed knowledge and skills of lone insiders suggest that these actors likely have the requisite capabilities to carry out deliberate acts in a high containment research laboratory. Non-punitive peer reporting of unusual incidents or repeated experimental findings, damaged equipment and facilities, and behavioral changes or unusual behavior of individuals with authorized access to high containment, research laboratories are the only measures that exist to prevent or mitigate a deliberate act carried out by an insider with trusted access.

When analyzing an actor's ability to access a high containment, research laboratory, the most likely malicious actors to carry out deliberate acts that could result in accidental release of virus are foreign intelligence agencies, transnational terrorists, domestic terrorist and extremist groups, and lone insiders.

- Research institutions supporting animal research and high containment research have access controls in place to protect laboratories. These controls can take the form of guards; electronic, biometric, or mechanical intrusion prevention systems; and/or some combination of these measures. Based on these access controls and periodic monitoring of access to laboratories, the likelihood that any outsider, who is not working with an insider, would gain access to the high containment, research laboratory to tamper with experiments involving GoF viruses or their wild type counterparts is low.

- Foreign intelligence agencies are known to elicit information from insiders as part of their typical tradecraft, suggesting the ability to achieve indirect access to laboratory materials. In addition, these agencies may have personnel who can gain authorized entry to the laboratories (i.e., insertion of an operative) for direct access to high containment laboratories. Professionals likely would not be identified by currently implemented personnel reliability measures at research institutions or deterred by access control measures. Foreign intelligence agencies also may have the resources to access laboratories remotely by hacking into laboratory computer systems.

Finally, foreign intelligence agencies may have the resources to detonate a bomb or carry out an armed assault, but as previously stated, these acts could be construed as an act of war.

- Transnational terrorists may have access to the exterior perimeter of the building in which a laboratory is located and potentially to the research laboratory itself, if access control measures are insufficient. However in general, such actors would not have access to the high containment laboratory itself unless assisted by an insider. Current personnel reliability measures that allow for periodic behavioral assessment, specifically implemented for Tier 1 BSAT, and non-punitive reporting of changes in co-worker behavior (any level of research) could alert institutional officials to possible radicalization of an insider. That said, colleagues may not recognize such changes or may be in denial that such changes are taking place in a friend or colleague.

- Historically, domestic terrorist and extremist groups, such as animal rights extremists, have recruited, elicited information from, and subverted insiders to gain access to animal facilities. In addition, other groups have elicited information about clinics as they prepared to bomb buildings based on historical examples. Domestic terrorist and extremist groups are likely to access the perimeters of buildings and low containment research laboratories, but not likely to access high containment research laboratories without the assistance of an insider.

- The likelihood that criminal organizations and lone outsiders would have access to high containment, research laboratories is low. However, the possibility that an insider could assist a criminal organization in carrying out a deliberate act in a high containment laboratory cannot be ruled out, though the exact purpose behind such an act is not clear.

- Lone insiders are extremely likely to have opportunities to tamper with experiments, release animals, compromise equipment, detonate bombs, and carry out armed assault in high containment, research laboratories because they have authorized access to these laboratories.

7.4.1.1.3 Malicious Actor Conclusion

When evaluating the intent, capability, and the ability to access laboratories in which GoF research with influenza virus, SARS-CoV, or MERS-CoV, the most likely malicious actors to target a US research laboratory to carry out a deliberate act to the building perimeter are domestic terrorists and extremists, transnational terrorists, lone outsiders, and lone insiders. Although no open source information indicates whether these malicious actors are motivated to damage buildings in which GoF viruses are stored or studied, historical examples of attacks involving other types of buildings do exist.

When looking at all three components together for deliberate acts carried out inside a high containment research laboratory in which GoF research with influenza virus, SARS-CoV, or MERS-CoV is conducted, the most likely malicious actor is an insider, working alone or in coordination with a group, particularly domestic terrorist or extremist groups.

7.4.1.2 Malicious Acts and Likelihood of Escape of GoF Virus

The likelihood of success of malicious acts and resulting virus escape are based on the degree of access to a high containment research laboratory. These laboratories (i.e., biosafety levels 3 and 4) have a variety of security measures in place to prevent unauthorized access by individuals who are not approved to work and/or do not demonstrate competency and proficiency in working safely and competently in the laboratory. In addition, researchers working with BSAT are subject to review by the Security Risk Assessment (Appendix V Section 16.11.2) and those working with Tier 1 BSAT must undergo periodic

screening assessments. Based on these physical and personnel security measures, the analysis of malicious acts is divided into: 1) acts that can be carried out by only insiders and 2) acts that outsiders can be carried out without insider assistance. The analysis draws upon historical cases to evaluate the likelihood that malicious acts would be undertaken successfully and to focus on those acts that likely could cause a breach leading to escape of a GoF influenza virus, SARS-CoV, or MERS-CoV. Table 7.4 summarizes the likelihood of an outsider or insider to successfully carry out a particular malicious act and the likelihood that such an act could lead to GoF virus escape.

Table. 7.4. Malicious Acts Undertaken and Likelihood of Success

		Outsider	Insider	Leads to GoF Virus Escape
Armed Assault				
Bomb				Depends of size, type, and location of a bomb blast
Arson				
Physical Entry			N/A	Unlikely by itself
Cyber Breach				
Theft of Virus	Infect Co-Workers			
	Infect Public			
Theft of Animals				
Theft of Materials, Equipment, or Information				
Sabotage				
Elicitation of Information			N/A	
Subversion of Employees			N/A	Unlikely by itself
Insertion of Operative			N/A	Unlikely by itself
Reckless Act				Depends on the act
Deliberate Self-Infection				

Black *indicates consistency of intent, capable, or able to access high containment, research laboratories with known malicious actor motivations and capabilities, and historical incidents.*

Dark ***Grey*** *indicates possible intent, capable, or able to access high containment, research laboratories with known malicious actor motivations and capabilities, and historical incidents.*

Grey *indicates inconsistency of intent, capable, or able to access high containment, research laboratories with known malicious actor motivations and capabilities, and historical incidents.*

Armed Assault

The increase in active shooter incidents in the US suggests that an armed assault in a high containment research laboratory may be possible at some level. Outsiders could carry out an armed assault outside the building in which GoF research is conducted. Insiders possibly could carry out an armed assault inside a research building and high containment research laboratory.

Current personnel security measures requiring periodic assessment of personnel and non-punitive reporting of behavioral changes in personnel could provide an opportunity for institutional officials to identify potential insider threats before acts are conducted. These measures are required for Tier 1 BSAT laboratories. In addition, institutions conduct emergency response exercises and many universities have threat assessment teams to evaluate the threats on campus and identify prevention strategies. Physical security measures, including physical barriers, access controls, and surveillance measures, work to prevent armed outsiders from gaining access to high containment, research laboratories. However, no physical security measures are in place that would prevent authorized insiders from taking guns into high containment research laboratories.

An armed assault leading to escape of a GoF virus is unlikely even if the assault is carried out successfully. Exposure to GoF virus through an open wound is unlikely to cause infection. However, active shooters inside a laboratory might lead to viral escape through accidental aerosolization of virus in experimental samples (i.e., exposing the shooter to aerosolized GoF virus or contaminating street clothing with fomites). If emergency personnel also enter the laboratory, they may be exposed to aerosolized virus or fomites if not wearing proper protection.

Bomb or Arson

Several historical cases exist of malicious actors detonating bombs in public areas, outside buildings, or at clinics or setting fires to research buildings. Although outsiders could detonate bombs outside of buildings or areas accessible to the public, they do not have access to high containment research laboratories unless assisted by an insider. Insiders potentially could detonate bombs inside research buildings or high containment research laboratories.

As with armed assault, current Tier 1 personnel security measures could provide opportunities to prevent insiders from successfully detonating a bomb or setting a fire in a research laboratory and building. Institutions conduct emergency response exercises and universities have threat assessment teams to evaluate the threats on campus and identify prevention strategies. Although physical security measures help prevent outsiders from gaining access to high containment research laboratories, these measures would not prevent authorized insiders from detonating bombs or setting fires in high containment research laboratories.

The size, type, and location of a bomb blast may lead to escape of GoF virus from experimental samples. If the size of the blast is sufficiently large to rattle the building infrastructure (to a similar degree as an earthquake), GoF virus might aerosolize from spilled experimental samples leading to possible loss of containment. Similarly, a blast that occurs at the entrance or inside of a high containment, research laboratory might result in aerosolization of GoF virus and compromise the negative pressure of the laboratory. However, arson is unlikely to lead to escape of a GoF virus even if carried out successfully because institutions have established procedures and response measures for fires and viruses are sensitive to high temperatures.

7.4.1.2.1 Physical Entry

By definition, insiders have authorized access to high containment research laboratories. Consequently, this type of act does not apply to insiders. Outsiders are unlikely to gain physical access to high containment, research laboratories without assistance from an insider.

Physical security measures employed at high containment research laboratories and animal facilities, including physical barriers, access controls, and surveillance measures, help prevent outsiders from gaining access to the laboratory itself.

Physical entry alone does not lead to escape of GoF virus from containment.

Cyber Breach

Over the past decade, a growing number of malicious actors, from nation-states to individuals, have hacked into computer systems in the pharmaceutical, health care, insurance, national security, and commercial organizations. Furthermore in 2010, a computer worm that infected the software of an Iranian uranium enrichment plant, in addition to other industrial sites, affected operations of Iranian nuclear centrifuges,[387,388] suggesting this attack approach should not be ruled out.

Outsiders or insiders with the requisite expertise could hack into the computer systems of research institutions. Other than firewalls, anti-virus software, and standard cyber security measures, no specific measure is required to protect information and infrastructure systems from cyber breaches. The exception is Biological Select Agents and Toxins laboratories, which are required to have information security in place to prevent cyber breaches.[389,390,391,392,393,394]

The likelihood that a cyber breach would lead to escape of GoF virus is moderate. However, breaches in infrastructure systems, such electronic controls for air-handling, could lead to escape pf a GoF virus from containment. That said, air-gapped systems (i.e., those systems that are not connected to the internet) are much less likely to lead to escape of GoF virus. Based on our interviews, systems that control laboratory operations, air filtration, and decontamination are not connected to the open internet, but this does not necessarily mean that the systems are immune to attack.

Theft of GoF Influenza Virus, SARS-CoV, or MERS-CoV

Theft of GoF virus could occur in two ways: 1) by stealing it from a high containment, research laboratory and 2) theft or diversion during transportation. Outsiders acting without the assistance of an insider likely are not able to steal GoF virus from high containment laboratories because of the various access control measures in place to prevent unauthorized access into these laboratories. The likelihood of an outsider stealing GoF virus during transportation is low primarily because knowing the transfer date,

394 7 C.F.R. §331.11(c)(9).

exact truck carrying the virus, and transportation line used would be extremely difficult without assistance by a knowledgeable insider.

The likelihood of an insider successfully stealing a GoF virus from a laboratory is high because, by definition, such an individual has authorized access to high containment research laboratories. Furthermore, insiders have used pathogens against co-workers, family members, and members of the public in the past. Current personnel security measures requiring periodic assessment and non-punitive reporting mechanisms could identify behavioral changes in personnel before an act is committed. Inventory measures could help identify discrepancies in stored GoF virus. However, theft of virus could occur in-between the regular inventory reviews, could be missed if virus is removed from vials, or could be via theft of experimental, infectious samples.

Theft of GoF virus leads to escape of virus from containment by definition, but such an act does not presume that the stolen virus could be used as a weapon. A significant amount of processing, including growth of the virus from a frozen stock, may have to be carried out to make the virus usable and/or disseminable. However, theft of experimental samples that contain GoF viruses might be used as is.

Theft of Animals

Several historical examples exist of domestic animal rights extremists removing animals from low containment research laboratories to take home as pets or release into the wild. However, no examples exist for high containment research laboratories or animal housing facilities, likely because of increased security and access controls of both facilities. The physical security and perimeter surveillance measures of facilities where research animals are present have increased to counter deliberate acts carried out by animal rights extremists. Current personnel security measures involving periodic assessment (as in Tier 1 BSAT) and non-punitive reporting mechanisms might identify insiders who have been elicited, recruited, or subverted by outsiders or decided to carry out a malicious act on his/her own. Vigilance by other laboratory workers could decrease the likelihood that animals go missing.

Theft of infected animals would likely lead to escape of GoF virus.

Theft of Materials, Equipment, and Information

Despite numerous historical cases involving deliberate acts carried out by domestic terrorists and extremists, none have involved high containment research laboratories. The historical cases evaluated involved assistance from insiders to provide information, enable access into laboratories, or carry out actual deliberate acts, such as theft of animals or vandalism of equipment. Physical barriers and access control measures prevent outsiders from gaining access to high containment research laboratories. Therefore, outsiders acting without insider-assistance are unlikely able to steal laboratory materials, equipment, and information contained in high containment research laboratories. Because insiders are authorized to access high containment research laboratories, the likelihood that they could steal materials, information, or equipment is high.

Current personnel security measures involving periodic assessment (as in Tier 1 BSAT) and non-punitive reporting mechanisms might identify insiders who have been elicited, recruited, or subverted by outsiders or decided to carry out a malicious act on his/her own. Vigilance by other laboratory workers could decrease the likelihood that equipment, materials, or information (e.g., laboratory notebooks or inventory logs) go missing.

Theft of contaminated equipment or materials might lead to escape of GoF virus. Theft of information would not lead to escape of GoF virus.

Sabotage

The likelihood that outsiders will tamper with equipment or experiments in high containment is low if not assisted by an insider. The likelihood that an outsider will tamper with the laboratory itself (including the HEPA filtration system and waste management system) is low unless such an individual has assistance from a knowledgeable insider. An insider with access to experiments and equipment could tamper with them. However, not all insiders have access to laboratory operating systems, reducing the likelihood of such acts.

Current physical barriers and access controls help prevent outsiders from gaining access to high containment, research laboratories, and their primary operating systems. Personnel security measures help identify insiders who might carry out acts of sabotage within the laboratory, against a facility, or in the laboratory operating system. However, these measures would not necessarily enable detection of insiders in a non-BSAT high containment research laboratory.

Sabotage of experiments, equipment, or laboratory operating systems might lead to escape of GoF virus. For example, tampering with laboratory materials could lead to ineffective decontamination of samples, which, if undetected, could result in accidental exposure of laboratory workers who don't realize the viral samples are still infectious. Other examples include removal of HEPA filters from the air flow system, which would prevent proper filtration of the laboratory air, or tampering with a centrifuge rotor, which could result in an imbalance during spins causing the contents to rupture and exposing laboratory workers to the infectious samples.

Reckless Act

Reckless acts include mixing of infected animals with uninfected animals to deliberately tamper with experiments. Several historical cases involving animal rights extremists suggest that these acts can be carried out in low containment research laboratories. However, the increase in physical barriers, access control measures, surveillance of animal facilities, and arrests have deterred such groups from carrying out these acts.

These types of reckless acts are highly implausible for GoF virus research, because infected and uninfected experimental animals are kept in high containment research laboratories, which often are in different locations than facilities housing uninfected animals that are not part of ongoing research. Consequently, the likelihood that an outsider could carry out such acts is low unless assisted by an insider. The likelihood that insiders who have been elicited, recruited, or sabotaged by an outside group could remove animals from high containment, research facilities is high. However, because animals involved in active experiments are separated physically from animals not involved in experiments suggests that mixing of infected and uninfected animals in lower containment is not as likely, though not impossible.

Physical barriers, access control measures, and surveillance of animal facilities and BSAT facilities help prevent outsiders from entering high containment, research laboratories unassisted. Current personnel reliability measures, including periodic assessment and non-punitive reporting mechanisms, help institutional officials to detect changes in behavior in personnel. However, these personnel security measures are required only for Tier 1 BSAT laboratories; some non-Tier 1 BSAT laboratories implement these measures on their own or as part of their institution's Tier 1 BSAT program, if applicable.

Reckless acts, such as removal of experimental animals, could lead to escape of a GoF virus via the infected animal. Mixing of infected and uninfected animals could lead to escape of a GoF viruses if the

uninfected animals are in low containment and in contact with people. Deliberate infection of oneself, co-worker, friend, or family member leads to escape of a GoF virus.

Deliberate Self-Infection

Two historical cases of deliberate self-infection exist; however, these cases do not involve self-infection with a virus taken from a research laboratory. Acts involving deliberate self-infection require an actor to obtain the GoF virus either from a high containment research laboratory. Outsiders acting without the assistance of an insider are not likely to obtain a GoF virus from high containment laboratories because of the various physical barriers and access controls in place at such laboratories. The likelihood of an outsider obtaining GoF virus during transportation is low primarily because knowing the transfer date, exact truck carrying the virus, and transportation line used is impossible without assistance by a knowledgeable insider.

The likelihood of an insider obtaining a GoF pathogen from the laboratory for use in self-infection is high because (s)he has authorized access to high containment research laboratories. Current personnel security measures requiring periodic assessment and non-punitive reporting mechanisms could identify behavioral changes in personnel before an act is committed. The benefit of inventory measures for acquisition of virus for self-infection is unclear. The insider likely would use experimental samples, which are not part of current long-term storage measures.

Deliberate self-infection of insiders would lead to escape of GoF virus from containment.

7.4.1.2.2 Malicious Act Conclusion

The most likely malicious acts that could lead to escape of a GoF virus from high containment research laboratories are: theft of GoF virus or contaminated equipment; tampering with experiments or laboratory operating systems; removal of infected animals; and deliberate infection of oneself, friend, family member, or co-worker. All of these acts involve insiders, who are either acting alone or in coordination with a group, such as domestic terrorist and extremist group. Whether theft of GoF virus leads to exposure and infection by laboratory workers or members of the public depends on the virus' form (either from frozen vials or experimental samples) and the skills and resources of the malicious actor to effectively grow and deliver the virus.

A possible malicious act that is less likely to lead to escape of a GoF virus is a bomb. The size and location of a bomb determines whether its detonation could lead to escape of GoF virus in experimental samples. Outsiders and insiders could detonate a bomb, though in different locations (i.e., outside the building or near a high containment, research laboratory).

7.4.1.3 Type of Breach Leading to GoF Virus Escape

The likelihood of virus escape and human infection caused by malicious acts are summarized in Table 7.5.

Table 7.5. Type of Breach Leading to Virus Escape

		Malicious Act	GoF Virus Escape	Human Infection
Loss of Containment	**Release of Infected Animals from and within Laboratories**	Theft of Animals Sabotage Reckless Act		
	Release of Infected Animals in the Environment	Theft of Animals Reckless Act		
	Cross-Contamination of Laboratory Animals	Sabotage Reckless Act		
	Exposure of Laboratory Workers (Could Include Emergency Personnel accessing the Laboratory)	Armed Assault Bomb Sabotage Reckless Act Deliberate Self-Infection		
	Removal of GoF Virus from the Laboratory	Theft of GoF Virus

Release of Infected Animals From and Within Laboratories.

The design of and security measures associated with high containment research laboratories help prevent unassisted escape of animals from the laboratory. However, if an insider intentionally releases laboratory animals outside of high containment research laboratories, the likelihood that animals will escape the building varies based on the number of released animals, the method of release, their ease of capture by researchers, and the design features of the facility, all of which either limits or permits animal escape. Furthermore, the number of people that the animal might encounter as it wanders around in the building affects the level of exposure these individuals have to GoF virus from infected animals. Because of this variability, the likelihood of GoF virus escape and human infection resulting from theft of infected animals from and within laboratories is moderate and depends on a variety of factors.

Release of Infected Animals in the Environment

Theft of animals would result deliberate release of infected animals into the environment, whether in the wild or someone's home (as a pet), and hence, would be considered as a GoF virus escape. Furthermore, the close proximity of the infected animal to the actor who releases the animal suggests that at least one human (the malicious actor) would be exposed to the GoF virus and could be infected.

Cross-Contamination of Laboratory Animals

Sabotage of experiments, including the deliberate mixing of infected and uninfected animals within high containment research laboratories, neither increases the likelihood of GoF virus escape, nor increases the likelihood of human infection. However, the deliberate mixing of infected and uninfected animals in lower containment research environments (i.e., sabotage) might expose researchers not protected against H5 influenza, SARS-CoV, or MERS-CoV to GoF virus and cause GoF virus escape if the virus gets on street clothing. The likelihood that this exposure could result in human infection depends on the level of exposure researchers have with the infected animals before the contamination is detected.

Exposure of Laboratory Workers.

Malicious acts involving deliberate or accidental exposure of laboratory workers could result in GoF virus escape if the exposed individual(s) gets infected with the GoF virus. Human infection may occur with virus from experimental samples, thawed virus, or fomites. If equipment or other materials are deliberately contaminated or tampered with and laboratory workers are not protected well (i.e., through use of the appropriate personal protective equipment), they may get infected with GoF virus in experimental samples. Consequently, the likelihood of human infection is moderate.

Removal of GoF Virus from the Laboratory.

By definition, theft of GoF virus from the laboratory results in viral escape. However, the degree to which GoF virus removal causes human infections depends on the form of the virus (i.e., either frozen virus or virus in experimental samples) and/or the skills, expertise, and resources of the malicious actor to grow or manipulate frozen viruses. Consequently, the likelihood of human infection is moderate.

Infection of Wild or Domestic Animals Following Deliberate Outdoor Release of GoF Virus.

By definition, release of stolen GoF virus from experimental samples, stocks grown from stolen virus, or stolen infected animals into the wild or households results in viral escape. The likelihood that a malicious insider would be able to make a sophisticated dispersal device and not be detected is low, suggesting that rudimentary dispersal devices may be the most likely route of release of virus. Furthermore, the likelihood that infected animals (domestic or wild) could cause immediate infection in humans is low because of the low level of interaction between wild animals and humans or domestic animals in urban settings. However, the zoonotic nature of the viruses (i.e., their ability to infect animals and at least some humans) does not automatically rule out the possibility of human infection ever.

Infection of Laboratory Workers or the Public following Deliberate Outdoor Release of GoF Virus

Exposure of laboratory workers or members of the public using stolen GoF virus from experimental samples or stocks grown from stolen virus results in GoF virus escape and human infection.

7.4.1.3.1 Type of Breach Conclusion

The most likely types of breach leading to human infection following a malicious act are release of infected animals, infection of laboratory workers following deliberate release of GoF virus, and infection of the public following deliberate release of GoF virus. However, successful release depends on form of the virus (i.e., frozen stock or experimental sample) and the skill-level of malicious actors (to grow virus from frozen stock). These breaches could only occur with the assistance of an insider or significant blast that affects the integrity of the laboratory.

Given the right circumstances, human infections might occur from release of infected animals from and within laboratories, cross-contamination of laboratory animals, exposure of laboratory workers, and removal of GoF virus from the laboratory. The number of people exposed in each of these cases is likely to be low, suggesting an even lower rate of infection among exposed individuals.[395]

7.4.1.4 Plausible Threats of GoF Viruses

The most plausible threats facing laboratories in which GoF virus research is stored or studies are those carried out by insiders, acting alone or in cooperation with a domestic terrorist group or extremist group. Insiders acting alone may be disgruntled, emotionally disturbed, or radicalized. Those cooperating with a group may be sympathetic to the group's cause, coerced, or subverted.

Most likely, insiders will commit acts covertly. Such acts would most likely expose a small number of people to GoF virus. If exposed individuals are familiar with the symptoms and disease progression of the viruses, they might seek help immediately if infected. If not (i.e., the general public), infections resulting from exposure could lead to secondary infections. In addition, insiders could use GoF virus to expose a large number of people.

Though less plausible, insiders might commit overt acts, such as arson, bombing, or armed assault. Some of these acts would not lead to GoF virus escape and human exposure. The assumption is that emergency responders and public health officials will respond quickly to overt acts involve active shooters, fire, or explosions.

Most acts involving malicious actors without insider-assistance are not plausible. However, outsiders, including transnational terrorists, domestic extremists, domestic terrorists, and lone outsiders, could carry out an armed assault or detonate a bomb at the building perimeter if they have access. Armed assault would not lead to GoF viral escape and human exposure. However, a bomb of sufficient size might affect laboratory operating systems, possibly leading to release of GoF virus from experimental samples. These acts are overt and would elicit response from emergency responders.

Table 7.6 summarizes the results of the analysis. These results provide the basis for epidemiological modeling of plausible security threats involving GoF virus.

[395] No known virus has 100% infection rate among exposed individuals.

Table 7.6. Plausible Threats Involving High Containment Research Laboratories That Store or Study GoF Viruses		
Overt	Insider	Active shooter or physical assault Bomb detonated near or inside high containment space
	Outsider	Bomb detonated at building periphery
Covert Act (Expose Public)	Insider	Removal of GoF virus (frozen stock or experimental sample), infected animals, or contaminated equipment
Covert Act (Expose Laboratory Workers)	Insider	Removal of GoF virus in experimental samples Deliberate contamination of personal protective equipment or laboratory equipment Deliberate compromise of laboratory equipment or personal protective equipment Mixing of experimental samples or animals into lower containment

In addition to these plausible threats, theft of information about research, facilities, hours of operation, and personnel records are likely by foreign intelligence or domestic extremist groups.

7.4.2 Semi-Quantitative Epidemiological Modeling of Security Risks

7.4.2.1.1 The Need for a Semi-Quantitative Approach

The section above identified malicious acts that could plausibly be caused by a malicious actor and lead to a loss of containment event. The variability in the manner through which these malicious acts could be executed and the unknown probabilities of success at each step precludes the designing of fault trees (as was done for accidents in the Biosafety Risk Assessment) for these malicious acts. That is, no evidence-based quantitative model can be designed to estimate the probability that a particular malicious event would be successful the amount of virus escaping containment from a successful malicious act. Moreover, the state of the threat information is such that even estimating the frequency with which these malicious events would be attempted would prevent open and transparent communication of the risks. For this reason, a semi-quantitative approach is leveraged that estimates the difference in consequences between a malicious act targeting a laboratory with wild type strains vs one targeting a laboratory with various GoF strains, assuming that the malicious act were successful in causing at least one initial infection. This section culminates with an estimate of the frequency with which these malicious acts must be successful for the biosecurity risk to approximate the biosafety risk (given the relative consequences of the two types of events). Throughout, the consequences computed from various events in Chapter 6- Biosafety Risk are used where appropriate.

In most cases, any GoF trait would increase risk by either increasing the chance that an outbreak, initiated by an infection caused by a malicious event, would escape local control to seed a global outbreak, or by increasing the consequences of a global outbreak. Two GoF traits theoretically could influence the chance that an initial infection outside the laboratory would occur due to the malicious act: 1) enhanced growth in culture (increasing the amount of contamination that could escape the laboratory) and 2) adaptation of avian influenza strains to mammals so that the median infectious dose is decreased.

The first part of this section evaluates the potential for these two phenotypes to influence the probability that an initial infection occurs. The sections that follow discuss how all other GoF phenotypes could affect risk of an outbreak should an initial infection occur.

7.4.2.2 Influence of GoF Traits on the Probability That an Infection Outside the Laboratory Would Occur from a Malicious Act

The phenotypes of enhanced viral growth in culture and adaptation to mammals have the potential to increase infection probability in loss-of-containment incidents. Of all of the pathogens assessed in this study, this section is relevant only to influenza. Coronaviruses are already adapted to human hosts and so this phenotype is meaningless for these pathogens. Moreover, coronaviruses already grow to high titers and for this reason, no GoF manipulation is necessary to enhance their growth. (In any case, should a scientist attempt to enhance their growth or decrease their infectious dose in people, the analysis herein would suggest that little biosecurity would inhere in these manipulations.)

Figure 7.6 explores the relationship of the amount of contamination released (which is influenced by the titer of the sample leading to the contamination) in two strains of influenza, one with a relatively high median infectious dose (like avian influenza—top panel) and one with a very low infectious dose (of 1.5pfu—bottom panel). Increasing the amount of pathogen escaping the laboratory by an order of magnitude increases the probability of at least one infection by roughly 10%. That is, if a strain grew to a 100-fold greater titer due to a GoF manipulation and that concentrated stock caused contamination that left the laboratory in a malicious act, the act would have only a 20% increase in the chance that an infection would occur. Unless a very little amount of contamination leaves the laboratory (less than 100 pfu), this increase in the contamination released would increase the overall chance that an infection occurs by less than a factor of two. Moreover, the analysis shown in Figure 7.6, assumes that an enhancement of viral growth leads to a similar increase in the contamination released. In reality, viruses that grow to a high titer are diluted for use in most experiments (such as plaque assays or challenge experiments) so only some cultures that could cause contamination would be at the greater concentration enabled by a GoF experiment.

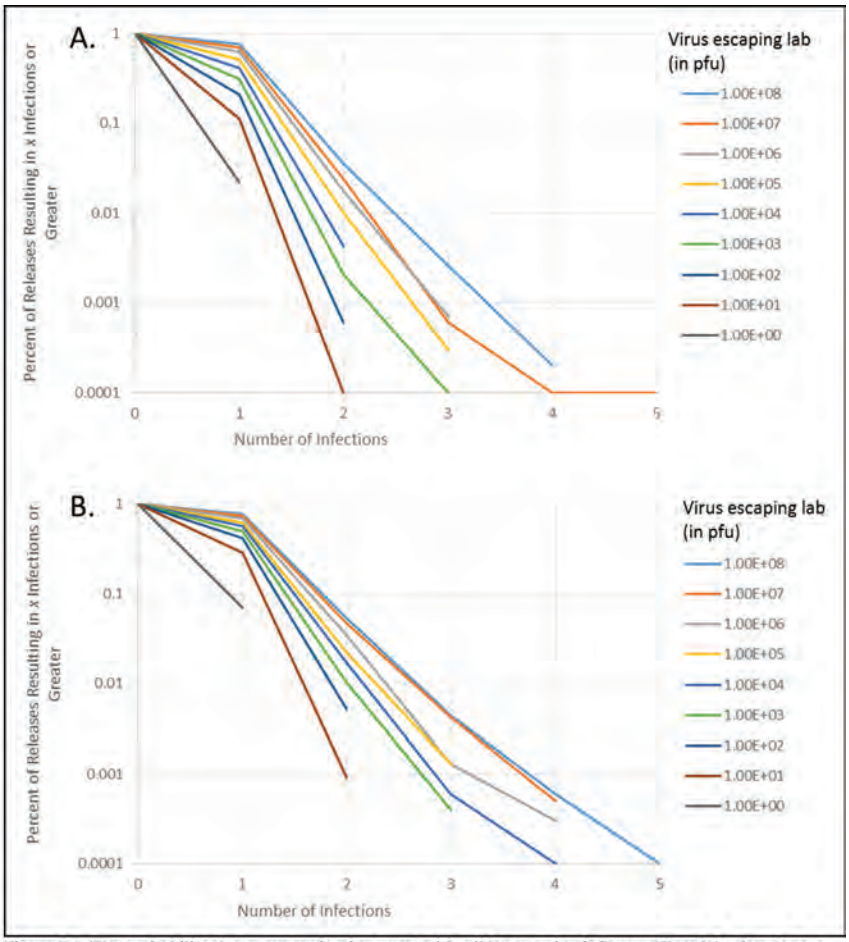

Figure 7.6. The probability that a contamination event with wild type avian influenza (Panel A, above), or a modified strain with a median infectious dose of 1.5pfu (Panel B, below) causes a certain number of infections when contaminated material escapes the laboratory for a variety of viral loads. The y-axis shows probability on a log scale with 1=100% certainty.

Comparing the panels in Figure 7.6. shows that the adaptation of avian influenza strains to mammals (resulting in a lower median infectious dose) would increase the probability that at least one person was infected by the contamination event by a factor of two or three. If just one pfu contaminates someone leaving the laboratory, one person would be infected about 7% of the time if the strain had a low infectious dose, compared to 2% if the strain were not adapted to humans. If the contamination involved

100 pfu, the chance of at least one infection would increase from 20% to 40% if the infectious dose were to decrease. However, strains adapted to humans are likely to be minimally infectious to birds and therefore malicious acts that involve the contamination of wild life (such as the release of infected birds) would be a lower total risk if this manipulation occurred. If the avian influenza strain were not also manipulated to be transmissible among humans, a malicious act resulting in the escape of contamination would sicken at most five people (Figure 7.6). In contrast, a strain that is not adapted to humans could cause an outbreak in avian species (if an infected animal were released, for example), which would lead to much more severe human health consequences (up to 1,000 illnesses and 100 deaths) than the direct infection of laboratory workers or the public by contamination. Recall that the biosafety risk assessment estimated that adaptation of an avian strain to humans (without increasing transmissibility) would *decrease* risk by a few fold because accidents that lead to an avian outbreak are much more likely than those that infect a person and avian outbreaks could lead to the deaths of many people, not just a single person infected in a laboratory. For this reason, because biosecurity events could lead to the infection of people or wildlife, we presume that adaptation to humans neither significantly increases nor decreases biosecurity risk.

Events that involve the release of contamination from the laboratory could also result in the infection of birds, although that chance is remote. Specifically, even assuming that 1E8 pfu of avian influenza escapes the lab on a single person's hand, the fomite model predicts that no infections would occur in chickens, ducks, or turkeys in 300,000 simulations. This result is not surprising because of the short half-life of influenza on the skin (on the order of minutes) and the rarity of laboratory workers physically handling poultry outside of a laboratory. No GoF phenotype would make the infection of birds from such a contamination event more likely or more extensive should it occur because wild type strains of avian influenza are already highly contagious and highly pathogenic in birds. The human health consequences from such an outbreak are estimated to involve 100 deaths and 1,000 illnesses.

7.4.2.3 Aligning the Malicious Acts to Biosafety Scenarios to Calculate Risk of Wild Type Agents

The probability that a malicious incident results in an outbreak that escapes local control depends heavily on who is initially infected (a laboratory worker or a member of the public), if the infection is related to an overt or covert incident and, to a lesser degree, how many people were initially infected. Events that initially target laboratory workers are of lesser risk than those that target the public because laboratory workers are more likely to be vaccinated against the strains in their laboratory, to self-monitor for initial signs of illness (like a fever), and to be isolated should an unusual illness manifest. If the event is overt and poses a high risk of causing an infection, the laboratory worker (or any person responding to an event in a laboratory) could be given antivirals prophylactically and also would be more closely monitored for the initial signs of illness (and could even be preemptively isolated).

Simply put, because of these four critical parameters, all malicious acts can be grouped into four categories to consider the risk of a global outbreak of a human transmissible disease: overt infections of laboratory workers, overt infections of members of the public, covert infections of laboratory workers, and covert infections of members of the public (Figure 7.7). For diseases that can spread amongst wildlife but not people (specifically, wild type avian influenza), a fifth group, malicious acts specifically infecting wildlife, is considered.

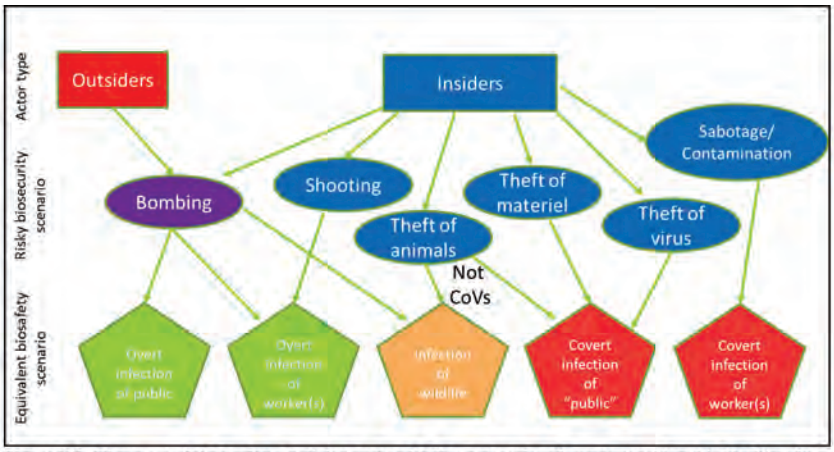

Figure 7.7. Alignment of the various malicious acts with five categories of events considered in the biosafety risk assessment. Because coronavirus strains that are modified to infect other animals pose a limited risk to people, we do not consider theft of animals is likely to cause an outbreak of human-transmissible disease.

7.4.2.4 Probability That a Malicious Event Would Lead to a Global Outbreak

From the Biosafety Risk Assessment in Chapter 6, we can determine the probability that an outbreak, caused by a malicious event, would lead to a global outbreak (Table 7.7). The table shows the probability that at least one secondary case would be caused and the probability that the outbreak would escape local control if laboratorians were infected or if members of the public were infected. Clearly, these probabilities are greatly influenced by how many people were infected by the initial event. Table 7.7 shows how these probabilities change if just one person were initially infected or several people were initially infected by the event. We assume that only five people in a laboratory could be simultaneously infected by an event due to the relatively small numbers of people working in a containment suite at any given time.

Table 7.7. Probability That the Initial Cases Lead to Secondary Infections, and the Probability That the Outbreak Escapes Local Control for Each Type of Event

Event Type		Seasonal Influenza		Pandemic Influenza		Avian Influenza		Coronaviruses	
Risk Type	**# of Initial Cases**	**Prob. of secondary spread**	**Prob. escapes local control**	**Prob. of secondary spread**	**Prob. escapes local control**	**Prob. of secondary spread**	**Prob. escapes local control**	**Prob. of secondary spread**	**Prob. escapes local control**
Infection of wild life		N/A	N/A	N/A	N/A	100%	100%	N/A	N/A
Covert infection of public	1	55%	20%	60%	20%	0%	0%	35%	0%
	10	100%	90%	100%	95%	0%	0%	100%	0%
Covert infection of worker(s)	1	15%	20%	20%	20%	0%	0%	2%	0%
	5	85%	90%	85%	95%	0%	0%	32%	0%
Overt infection of public	1	30%	20%	40%	20%	0%	0%	25%	0%
	10	100%	90%	100%	90%	0%	0%	100%	0%
Overt infection of workers	1	1%	20%	1%	20%	0%	0%	1%	0%
	5	3%	90%	3%	90%	0%	0%	5%	0%

Events involving wild type viruses highlighted in yellow have a relatively low probability of causing a pandemic and therefore offer an opportunity for GoF manipulations to increase risk.

As can be seen from the table, events that lead to at least one infection in members of the public are five- to 30-fold more likely to initiate a local outbreak than those that infect laboratory workers. Events that covertly infect laboratory workers are 10- to 20-fold more likely to initiate a local outbreak than those that overtly infect laboratory workers. This analysis permits a relative ranking of the risk (assuming the probabilities of the relative chance of success and the frequency of the malicious acts are unknowable), which is shown in Table 7.8.

Table 7.8. Relative Risk of the Plausible Malicious Acts Given an Unknown Frequency of Occurrence and Probability of Success

Risk Category	Primary Infection	Overt vs Covert	Event
Highest	Public or Wildlife	Covert	Theft of animals
Highest	Public	Covert	Theft of equipment, theft of virus
Moderately High	Public or Wildlife	Overt	Bombing
Moderately Low	Laboratorians	Covert	All events that lead to the infection of co-workers directly or indirectly
Lowest	Laboratorians	Overt	Shooting

Events that lead to an infection of wildlife are relatively low risk because those cannot seed a global pandemic of a human transmissible disease.

The potential for GoF phenotypes to increase the probability that a global outbreak occurs following an infection initiated by a biosecurity event is taken directly from the Biosafety Risk Assessment (Chapter 6 and summarized in the Stop Light Chart shown in Figure 7.8). This figure shows that transmissibility is the trait that can most affect the probability that the outbreak would escape local control, and this statement holds true for all pathogens evaluated. For seasonal and pandemic influenza, the ability to evade residual immunity or an increase in transmissibility to that of newly emergent pandemic influenza strains would increase the probability of a global outbreak. The relatively low risk that an infected laboratorian would infect another person is due to robust health monitoring and isolation protocols. GoF traits do not reduce the ability of these measures to mitigate an incident. If the strain were more pathogenic, perhaps the public fear elicited would improve social distancing measures and *decrease* the probability that an outbreak is contained, but this possibility cannot be directly evaluated. The ability to overcome protective vaccination and antiviral resistance independently modestly increases the chance that an infected laboratory worker would cause a secondary infection, so this trait has minimal influence on risk. Lastly, no explicit plans exist for the extensive use of antivirals in an outbreak associated with a laboratory, so the role of antivirals in a nascent outbreak could not be determined.

GoF Phenotype	Seasonal Influenza Viruses	Pandemic Influenza Viruses	Avian Influenza Viruses	Coronaviruses
Enhanced transmissibility				
Enhanced pathogenicity	Unknown	Unknown		
Adaptation to mammals	N/A	N/A		N/A
Evasion of induced immunity			N/A	N/A
Evasion of natural/residual immunity			N/A	N/A
Antiviral resistance				N/A
Enhanced growth in culture/eggs	N/A	N/A	N/A	N/A

Figure 7.8. A chart showing the relative increase in the probability that a global outbreak would occur for a variety of pathogens with GoF traits compared to the same strains with wild type traits. Darker grey denotes increasing risk. Green indicates that the phenotype does not increase risk for that pathogen.

Since wild type avian strains are not transmissible among people, the hazard ends with those initially infected by the event unless wild birds are infected (causing a global avian outbreak) or the strain is modified to transmit among humans. If the strain were modified to be as transmissible in humans as seasonal or pandemic influenza, the risk of a global outbreak would be significant. For this reason, GoF studies that increase the transmissibility of avian strains in humans significantly increase the probability that a global outbreak would occur. No other GoF traits affect the probability that an outbreak seeds a global pandemic for avian influenza.

Similarly, the coronaviruses are insufficiently transmissible to have a significant chance of seeding a global pandemic. Strains with enhanced transmissibility increase the chance that an outbreak occurs and that this outbreak sparks a global pandemic.

7.4.2.5 The Influence of GoF on the Consequences of a Global Pandemic

Should a global outbreak be sparked by a malicious act targeting a laboratory, the consequences would be similar to a global outbreak sparked by an accident in a laboratory and the influence of GoF traits on risk would be identical to those explored in Chapter 6. Figure 7.9 summarizes those findings.

GoF Phenotype	Seasonal Influenza Viruses	Pandemic Influenza Viruses	Avian Influenza Viruses	Coronaviruses
Enhanced transmissibility				
Enhanced pathogenicity				
Adaptation to mammals	N/A	N/A	N/A	N/A
Evasion of induced immunity			N/A	N/A
Evasion of natural/residual immunity			N/A	N/A
Antiviral resistance				N/A
Enhanced growth in culture/eggs	N/A	N/A	N/A	N/A

Figure 7.9. A chart showing the relative increase in the probability that a global outbreak would occur for a variety of pathogens with GoF traits compared to the same strains with wild type traits. Darker grey denotes increasing risk. Green indicates that the phenotype does not increase risk for that pathogen.

For seasonal and pandemic influenza, antiviral resistance and the ability to overcome protective vaccination would not significantly increase deaths from an outbreak globally, but would increase deaths by a few fold in North America due to the availability of these countermeasures in the US. Note, however, that to effectively evade the protection afforded by a vaccine raised in response to a particular outbreak, the strain must be modified to overcome vaccination regardless of its antigenic profile, which is not a subject of active GoF research. Increasing the transmissibility (or, similarly, imbuing the ability to evade residual immunity) of seasonal or pandemic influenza can increase global deaths. Given the relatively low case fatality rate of seasonal influenza, significant increases in pathogenicity (10x or more) are possible and these would proportionally increase the death toll.

A wild type avian influenza strain can infect people only via contact with infected birds, resulting in a few thousand cases at best. Given that many strains are minimally pathogenic, increasing the pathogenicity in people could increase these deaths by a few fold. In contrast a strain modified to be transmissible in people could cause a global outbreak, infecting millions and therefore significantly increasing risk. Increasing pathogenicity could increase global deaths by a few fold.

The wild type versions of the coronaviruses are insufficiently transmissible to have a significant probability of causing a global outbreak, or, if they do, the consequences are relatively small. Increasing transmissibility of these strains

7.4.2.6 Overall Influence of GoF on Risk of Biosecurity Events

In summary, only a handful of GoF traits significantly increase biosecurity risk after a malicious event targets a laboratory. For seasonal and pandemic influenza, the ability to overcome protective vaccination and antiviral resistance modestly increases risk by increasing the potential consequences in North America. No significant effect on risk exists if the global population is considered as a whole. Increasing the transmissibility and ability to evade residual immunity significantly increases risk because outbreaks are more likely to occur, escape local control, and create more consequential global outbreaks.

For avian influenza, increasing transmissibility greatly increases risk because this modification is required to spark a global outbreak of a disease by human-to-human contact, potentially infecting millions. Without this change, the hazard is restricted to those exposed to contaminated materials and infected birds, limiting the outbreak to thousands of cases at most. Increasing pathogenicity can modestly increase risk.

Similarly, the wild type coronaviruses have a very small chance of sparking a global outbreak so increasing transmissibility greatly increases risk. Increasing pathogenicity can modestly increase risk.

7.4.2.7 Comparison of Risk of Biosecurity Events Versus Biosafety Events

To understand the biosecurity risk of acts targeting a GoF laboratory relative to the risk of accidents with the same pathogens, this section provides data on the approximate frequency that various malicious acts must successfully result in an infection to match the risk of an *accident* involving the same pathogen. To accomplish this, estimates of the probability that a laboratory acquired infection sparks a global pandemic from the Biosafety Risk Assessment in Chapter 6 are combined with historical rates of laboratory acquired infections. Figure 7.10. shows the return frequency of a laboratory acquired infection in any one of the approximately 100 laboratories that study influenza or the coronaviruses in the US given that no laboratory infections have occurred in the last 20 years (or assuming that a few have occurred that we have not identified).

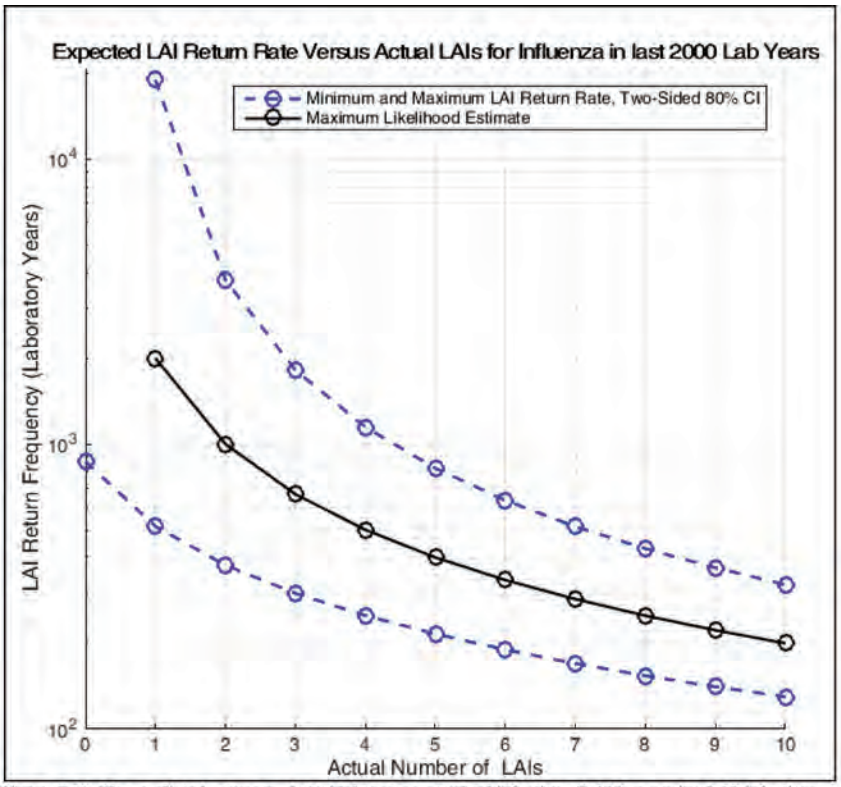

Figure 7.10. The predicted return period of laboratory acquired infections (LAIs) assuming 0-10 infections have actually occurred in the last 20 years across 100 laboratories. The 90th percentile of the maximum rate (bottom line) was used to produce an estimate of the return period that would greater than 90 out of 100 estimates of the frequency, whereas the maximum likelihood estimate and 90th percentile of the minimum rate (top line) is also shown.

A laboratory acquired infection is expected to occur every three to 200 years across all laboratories in the US. For simplicity, all these infections are assumed to be in laboratories that study seasonal influenza, since these vastly outnumber the laboratories that study other pathogens, and this work can be done at BSL-2, which allows more laboratory acquired infections to occur compared to BSL-3. (Highly pathogenic avian influenza, SARS-CoV, and MERS-CoV are studied in BSL-3 laboratories suggesting that the calculated number represents the upper bound of laboratory acquired infections for these agents.)

As described in the Biosafety Risk Assessment (Chapter 6), only about 0.5% of these laboratory infections are predicted to cause global pandemics due to public health response measures, stochastic factors, health monitoring, and isolation protocols. For this reason, a global pandemic due to a laboratory accident is expected to occur every 750-50,000 years.

Given that the highest risk biosecurity events (theft of animals, materials, or stocks by an insider) are also among the most plausible and that these events lead to covert infections of the public, the chance that a biosecurity event that infects one person leads to a global pandemic is much greater than the chance of an accidental laboratory acquired infection (since these may be overt and nearly always infect laboratory workers). If an infection occurs, biosecurity events have an 11% chance of starting a global pandemic (55% chance of initiating an outbreak and a 20% chance that this outbreak escapes local control).

For a biosecurity event to have the same total risk as biosafety events, a successful event that covertly infects the public (theft from an influenza laboratory of an infected animal, contaminated piece of equipment, or viral stock) must occur once every 80-5,500 years (11% of 750-50,000). Given the frequency with which thefts have been perpetrated by insiders in laboratories, this analysis suggests that biosecurity considerations be given as much weight as biosafety issues.

8 Biosecurity Risk of GoF Information

8.1 Summary

In this section, we analyze the risk that a malicious actor might misuse the information in publications describing GoF research. This analysis is based on the open-source literature covering desirable characteristics of biological agents and the scientific literature on GoF studies and non-GoF studies with significant dual-utility. We employed the NSABB definition of GoF research to delineate the dual-use phenotypes considered.[396]

We assessed the potential biosecurity information risk that could be generated by GoF information compared to what could be achieved through dual-use studies that do not rely on GoF research. We then assessed whether the unique dual-use information resulting from GoF studies had already been published. We find that little information risk remains from GoF research (see Figure 8.1). Although the development of a highly-contagious, highly virulent strain of influenza presents significant biosecurity information risk, the methods to produce these strains have already been published and so no information risk remains. Moreover, the specific changes in the genome that led to these traits have also been characterized and published, so an actor could reproduce the dual-use strains using reverse genetics. Although several potentially dual-use studies have already been published, translating animal studies of transmissibility to empirically predict an exact R_0 in a human outbreak is currently impossible; therefore, we cannot determine if the studies already published could be used to create strains of influenza that could cause a global pandemic (R_0 of greater than one). If not, further studies on this topic could create an information risk.

Similarly, information on how to develop strains of influenza viruses that grow well in culture/eggs or evade medical countermeasures or diagnostics has some dual-utility, but the methods to create these strains also have already been published.

[396] Framework for Conducting Risk and Benefit Assessment of Gain-of-Function Research: Recommendations of the National Advisory Board for Biosecurity. May 2015. http://osp.od.nih.gov/sites/default/files/resources/NSABB_Framework_for_Risk_and_Benefit_Assessments_of_GOF_Research-APPROVED.pdf

Dual-Use GoF Phenotype	Seasonal/Pandemic Influenza	Coronaviruses
Enhanced transmissibility in mammals		
Enhanced pathogenicity in mammals	Published methods require skills in molecular biology or were in poor animal models of pathogenicity. No publications exist on creation of influenza strains that lead to chronic illness.	
Enhanced transmissibility while maintaining pathogenicity		
Overcoming natural or induced immunity	Via the creation of antigenically distinct strains only	N/A
Evading diagnostics		The evasion of diagnostics that target the genomic sequence of the virus may pose an information risk.
Antiviral resistance		N/A
Enhanced production in cell culture or eggs		N/A

Figure 8.1. Summary of the information risk posed by GoF research in influenza (middle set of columns) and the coronaviruses (right set of columns). Information that has a significant dual-use (from Figure 8.2) AND is not yet published (Figure 8.3) is shaded darkly because it poses a remaining information risk. Information that is not actually dual-use OR has already been published is left white because it poses no remaining information risk. Information shaded gray may have some remaining information risk under some circumstances. N/A denotes traits that are not applicable to the coronaviruses.

Significant information risk would be realized by the publication of methods to create a highly transmissible SARS- or MERS-coronavirus that maintains its pathogenicity. Notably, without an animal model of transmissibility for these pathogens, this information risk is unlikely to be realized in the near future. A modest information risk inheres in methods to manipulate the genomic targets of a diagnostic assay for coronavirus infections without compromising the other desirable traits of the pathogen.

A modest information risk would be realized if researchers published methods to produce strains of influenza viruses that can produce more prolonged or chronic illness. Although this manipulation is a possible enhancement of pathogenicity that can fall under the definition of GoF research, there is little scientific rationale to undertake these experiments. Hence, the possibility that this information risk will be realized is low. Another modest information risk inheres in the publication of methods to produce strains of influenza virus that are able to overcome protective vaccination even if the vaccine matches the serotype of the pathogen. Similar work has been published for other pathogens, but these pathogens have larger and more plastic genomes than the influenza viruses so it is not known if similar manipulations could be successfully carried out in the influenza viruses.

State actors (and the sub-state groups they sponsor) are currently the only groups with the resources, expertise, motivation, and time to leverage this dual-use information. These states could protect their own populace from a global pandemic by secretly stockpiling vaccines that are protective against their modified strain. For this reason, states would be more likely to produce modified influenza viruses than coronaviruses (because no vaccines exist for this type of agent) and would probably be uninterested in developing strains able to overcome any vaccine (as this strain would vitiate their comparative

advantage). Sub-national malicious actors may obtain the capability to replicate some of the less complex GoF studies, but have so far not demonstrated any capacity to work with viral agents and little capacity for waging biological warfare in general. Highly skilled individuals trained in biology would be capable of replicating GoF studies, but are currently constrained greatly by a lack of material resources and time

Finally, no information risks unique to GoF research were identified. Similar techniques to those used in GoF experiments could be leveraged for other pathogens to create a highly transmissible strain of an already deadly virus (like the Hendra and Nipah viruses) or to create a deadly strain of an already highly transmissible pathogen that has been modified to overcome protective vaccination (polio-, mumps-, or measles-virus). Perhaps most worryingly, reverse genetics techniques could be used to synthesize smallpox virus if an actor has significant molecular biology skill, and this strain could be modified to overcome protective vaccination. Non-GoF pathogens could be used to produce effective, novel incapacitating agents by the modification of a highly contagious virus (polio-, mumps- or measles-virus) to overcome protective vaccination.

8.2 Purpose and Approach

The purpose of this task is to identify those GoF studies on influenza, SARS, and MERS viruses that, if published, would provide useful information to a malicious actor seeking to create a biological weapon. This analysis assumes that the body of dual-use information already in the public domain is significant and so seeks to identify studies that would contribute to the ability of a malicious actor beyond what has already been published. Since an adversary is presumably interested in causing harm in any way possible, this analysis considers GoF studies on influenza, SARS-CoV, and MERS-CoV in light of what can already be achieved with unmodified strains of these pathogens and non-GoF pathogens. Indeed, the capability to cause harm with agents other than influenza virus, SARS-CoV, and MERS-CoV is significant. Hence, this comparative assessment must be conducted to understand the advantage an adversary gains by leveraging the information gleaned from GoF studies, specifically. Lastly, to provide insight into the possibility that novel, dual-use information would be exploited if it were published, this study examines the capability and motivation of malicious actors to weaponize pathogens.

8.3 Methods

8.3.1 Use of Sources

This biosecurity information risk assessment involves the analysis of the biosecurity risk posed by the future publication of GoF research results beyond the existing dual-use information already in the public domain. This analysis uses scientific data to identify potential new capabilities afforded by GoF research to those who seek to cause harm. Biomedical literature describes the infectiousness, pathogenicity, and countermeasure resistance of wild type pathogens, and potential modifications to pathogens to enhance any of these traits. Information from intelligence/law enforcement data was used to provide the general context necessary to understand the capabilities of malicious actors to exploit this research but could not be directly reported at an unclassified level. Beyond this contextual level of discussion, we relied on open-source information on offensive biological weapons programs undertaken by states and non-state actors to source our analysis of malicious actor intent and capability.

8.3.2 Methodology for Baselining the Biological Threat

We first conducted an analysis of the biomedical literature and open-source descriptions of state-sponsored offensive weapons programs to determine what a malicious actor using unmodified agents

could achieve. We then examined how GoF pathogens could provide *additional* capabilities to an adversary. In this analysis, we considered the ability of various pathogens to incapacitate and kill as the possible desired outcomes of a biological attack. Attacks targeting animals for the purpose of causing economic harm or harm to animal health were outside the scope of the assessment. We also considered the "footprint" of the attack, meaning the area and time over which the attack would incapacitate or kill (under the assumption that a larger area or time of effect was desirable). Contagiousness of GoF pathogens is considered in this context. Given this baseline, our analysis identifies the type of information created via GoF studies that would prove useful to adversaries seeking to build additional biological weapon capabilities.

One quantitative method was used to baseline the threat. To quantitatively assess the dual-utility of the phenotype of enhanced growth, we compared how the number of victims infected from an intentional release scaled with the total amount of pathogen aerosolized, which itself is a function of how much pathogen can be produced. To perform this assessment, we used the Hazard Prediction and Analysis Capability (4.0) as described in the Risk Assessment of Accidents and Natural Disasters section above. We modeled only New York City as the target (due to its population density) across 12 different weather conditions for each release amount to show the maximum extent of a large attack.

8.3.3 Methodology for Baselining the State of the Science

Given that very little can be done about the dual utility of studies already published, we characterized the state of the science regarding the enhancement of all traits described in the NSABB framework. We analyzed the body of literature that encompasses all GoF studies identified by the project team for the benefit assessment and/or risk assessment (see bibliography). Specifically, we sought to understand to what degree the methods for the creation of modified strains of influenza viruses and coronaviruses with the following phenotypes already exist in the public domain:

- Enhanced production of pathogens *in vitro* or *in ovo* (high titer),
- Enhanced mortality,
- Enhanced morbidity,
- Enhanced transmission in mammals,
- Evasion of natural or induced immunity, and
- Evasion of medical countermeasures, including vaccines, antivirals and diagnostics.

This task culminated with the identification of GoF research that would provide uniquely valuable information to a malicious actor for misuse beyond the body of dual-use research that already exists. Also, we identified whether dual-use information already in the literature requires a particularly challenging technical approach in order to ascertain if a biosecurity information risk could be suffered via the publication of an easier experimental route to the same product. Similarly, instances in which the researchers published the specific genetic changes leading to the desired traits are noted because a malicious actor could simply recreate the useful strains using reverse genetics instead of repeating the methods. This section highlights which of the phenotypes described under the funding pause have yet to be achieved in the published literature, representing a remaining, possible information risk.

8.3.4 Evaluation of the Capability and Intent of Malicious Actors to Leverage Dual Use Information

We used open-source information to characterize the technical skill, sophistication, and resources required to replicate those GoF experiments that provide information uniquely useful and of interest to a malicious actor. We relied on historical precedent, as documented in open source information, in

considering whether certain malicious actors might have intent to leverage uniquely dual use information yet to be published.

8.4 Baselining the Biological Threat

When considering the information produced by GoF experiments, we considered how the results achieved intersect with the goals of those wishing to misuse the information. As in other sections of this report, we used the NSABB definition of GoF research for this analysis.[397] Specifically, we consider various strains of seasonal, pandemic, and avian influenza and the MERS and SARS coronaviruses. The phenotypes we consider are:

- Enhanced production of pathogens *in vitro* or *in ovo* (high titer),
- Enhanced mortality,
- Enhanced morbidity,
- Enhanced transmission in mammals,
- Evasion of natural or induced immunity, and
- Evasion of medical countermeasures, including vaccines, antivirals and diagnostics.

From the perspective of an adversary seeking to create a biological weapon (called a "weaponeer") these phenotypes can be described by three agent/weapon characteristics. **Mortality** covers the GoF phenotype of enhanced mortality and the ability of a pathogen to evade medical countermeasures and natural or induced immunity, as its ability to do so increases the overall case fatality rate. **Incapacitation** covers the GoF phenotype of enhanced morbidity, but also the phenotypes describing the evasion of medical countermeasures and natural or induced immunity, as these abilities increase the attack rate or the severity or duration of illness. **Footprint**—the ability of a weapon to cover an area, extend a pathogen's effects over time, or to reach a set number of victims—encompasses several GoF phenotypes. A strain with enhanced production characteristics can be used to increase the effective payload of a weapon (i.e., the same production run can produce more pathogen), potentially infecting more victims and covering a larger area when the agent is released using a weapon. A highly contagious GoF strain increases the footprint of an attack by increasing the number of victims harmed after the primary aerosol, which, in turn, increases the geographic and temporal extent of the effects. Similarly, a strain that evades medical countermeasures increases the number of victims potentially harmed by the primary aerosol. For contagious strains, the evasion of medical countermeasures also increases the attack rate and geographic and temporal extent of a resulting outbreak compared to an outbreak that can be effectively controlled by medical countermeasures.

To understand how GoF research could provide information that increases the ability of a weaponeer to produce a weapon that is highly lethal, highly incapacitating, or has a large footprint, we compare these GoF outcomes with what is possible without GoF research. We first consider the phenotypes separately and then consider under which circumstances the combination of traits leads to a particularly useful strain.

[397] Framework for Conducting Risk and Benefit Assessment of Gain-of-Function Research: Recommendations of the National Advisory Board for Biosecurity. May 2015. http://osp.od.nih.gov/sites/default/files/resources/NSABB_Framework_for_Risk_and_Benefit_Assessments_of_GOF_Research-APPROVED.pdf

8.4.1 Mortality from Diseases Caused by Non-GoF Pathogens

Without any information from GoF research, a weaponeer can choose from several agents that cause diseases with extremely high mortality rates, which can be identified simply by scrutinizing the Select Agent list.[398]

8.4.1.1 The Bacterial Agents

Several diseases caused by bacterial agents have an extremely high case fatality rate. Inhalational anthrax has an untreated case fatality rate of 90% and a treated case fatality rate of approximately 50% if aggressive treatment is provided.[399] Melioidosis has a case fatality rate in western countries of about 15%, although many of the victims have significant co-morbidities.[400,401] Pneumonic plague is almost uniformly fatal if untreated.[402] Although the untreated case fatality rate of the typhoidal form of tularemia is about 30%, animal studies suggest that high doses that may be experienced in the context of a biological attack significantly increase the lethality of this agent.[403,404]

Because all of these agents are bacteria that can replicate outside of a host cell, a weaponeer would likely find isolating, growing, and weaponizing these agents easier than the influenza viruses and coronaviruses.[405] Also, since many of the bacterial Select Agents featured in the offensive weapons programs of several states, information on their efficient weaponization already could be available or obtained by state actors.[406,407,408]

From a weaponeer's perspective, the disadvantage of using bacterial agents is that the diseases they cause can be prevented or effectively treated with antibiotics. However, simple molecular or microbiological methods (such as selection *in vitro* or *in vivo*) can be used to induce significant resistance in these bacteria to a panel of therapeutically useful antibiotics. Moreover, the methods to eliminate the fitness defect associated with newly acquired antibiotic resistance (or indeed any newly acquired phenotype) also involve relatively simple microbiological manipulations. In short, when compared to methods related to

GoF, a weaponeer can much more easily obtain a highly lethal strain of bacteria via simple methods of manipulation.

8.4.1.2 The Viral Agents

Several viral agents on the Select Agent list are associated with a high case fatality rate. The Hendra and Nipah viruses have a case fatality rate of roughly 50%, with no effective treatment.[409,410,411,412] Marburg virus, a hemorrhagic fever virus (HFV) on the Select Agent list that was weaponized by the Soviet Union, had a 22% case fatality rate in Europe during its initial outbreak and rates above 80% in subsequent outbreaks in the developing world.[413,414] Hemorrhagic fever case fatality rates are worsened by the difficulty of applying proper clinical care management and the lack of non-experimental treatments with demonstrated efficacy.[415] Since Marburg HFV featured in the offensive biological weapons program of the Soviet Union, a malicious state-level actor may be able to access the methods to magnify and weaponize this agent.[416] Although not a select agent, rabies virus causes a nearly uniformly lethal infection if not prevented by vaccination soon after exposure. Finally, while currently circulating strains of H5N1 avian influenza are associated with a fatality rate of 60%, this rate may be inflated due to potentially unreported cases of mild illness in this outbreak.[417,418] SARS and MERS outbreaks are associated with a case fatality rate greater than 10% as well, albeit mostly in the elderly (see Section 4).[419] In short, a weaponeer can use a variety of wild type viruses if high mortality is desired without resorting to the exploitation of more sophisticated GoF methods.

> Several bacterial and viral agents give the weaponeer a choice of pathogens that are highly lethal without relying on information from GoF experiments.

8.4.1.3 Toxins

Several toxins are listed on the Select Agent list.[420] These toxins are highly deadly and lack effective treatments for victims who have received a sufficiently large dose. Extracting or otherwise producing enough toxin from biological organisms to inflict a mass casualty requires industrial-like production capacity. That being said, several state actors and one sub-state actor have invested in the capacity to

produce toxins in quantities useable in weapons.[421,422] Therefore, for adversaries willing to invest in industrial scale production of toxins, GoF information provides little value for achieving a highly lethal agent because toxins are already very deadly.

8.4.2 Incapacitation from Diseases Caused by Non-GoF Pathogens

Some biological weapons are not designed to kill, but rather to incapacitate the soldiers or industrial workers of an enemy. In fact, incapacitating agents were featured heavily in the now defunct US offensive biological weapons program.[423] Due to their high case fatality rate, MERS and SARS coronaviruses cannot be considered incapacitating agents and are not discussed further in this section. The effectiveness of an incapacitating agent can be described by three characteristics: the infectious dose, the severity of the symptoms, and the duration of incapacitation.

Wild type strains of the incapacitating agents weaponized in the former US offensive biological weapons program, such as *Coxiella burnetii*, have a number of characteristics that make them suited for this purpose. The median infectious dose in humans of *C. burnetii* is less than ten microbes, which is comparable to the most infectious strains of influenza and the coronaviruses and provides little opportunity for improvement utilizing information from GoF studies.[424] The symptoms of the acute disease caused by infection with *C. brunetii*, called Q fever, are similar in severity and type to influenza, including a high fever (up to 105°F), pain, headache, malaise, vomiting, and diarrhea.[425] These symptoms persist longer than the symptoms of influenza, with fever typically lasting longer than ten days (fever in influenza lasts typically half as long—see Supplemental Information on the disease course of influenza).[426] Moreover, some victims develop a chronic form of Q fever with long-lasting and recurrent disabling symptoms.[427] Antibiotics can be used to effectively treat the illness, but, as described above, antibiotic resistance can be imbued into this agent using methods much less technically challenging than those necessary to undertake GoF studies. Moreover, because *C. burnetii* was weaponized in the former US weapons program, the information needed to grow and weaponize this agent could be leveraged by an adversary.[428,429] In short, GoF studies with the influenza viruses are unlikely to lead to the development of a pathogen that is more effective as an incapacitating agent than *C. burnetii* because this agent is highly infectious and produces a severe, relatively long-lasting illness. The only caveat is that influenza infections have a relatively fast symptom onset time compared to *C. burnetii* infections (an average of two days for influenza infections, versus two to three

> GoF studies with the influenza viruses are unlikely to lead to the development of a pathogen that is better as an incapacitating agent than *C. burnetii*, unless rapid symptom onset times are desired by a malicious actor above all other characteristics.

weeks for acute symptom onset for *C. burnetii* infections), and a malicious actor that strongly values rapid effects over other weapons characteristics may favor influenza. In this case, wild type influenza viruses may be considered nearly ideal.[430]

8.4.3 Footprint of Attacks of Non-GoF Pathogens

As described above, the footprint of an attack is defined as the number of victims affected, the physical area affected, or the duration of the disruption directly caused by the attack. In Section 8.4.3.1 below, we explore how GoF phenotypes could affect the footprint of a weapon. In this section, we explore how wild type pathogens and existing technology can create large footprint attacks.

The biological agent that most notoriously embodies attributes desirable for large footprint attacks is *B. anthracis*, which led to its inclusion in several state offensive weapons programs.[431,432,433] The spores formed by *B. anthracis* are extremely resistant to environmental forces and can survive for a long time suspended in an aerosol.[434] This pathogen is able to create large footprint attacks, which is demonstrated by the use of the related organism, *B. thuringiensis*, in pest control programs involving the treatment of square miles of territory with spores dispensed from a single vehicle.[435] If dispersed by sophisticated maritime, ground-based, or aerial platforms, *B. anthracis* could cover thousands of square miles and reach millions of people with a single attack (as demonstrated by a series of pre-1969 US tests using simulants, such as Operation Large Area Coverage).[436,437] Although the biological properties of non-contagious agents can *facilitate* their use in a weapon that can attack large areas, the ability of a non-contagious agent to reach these large areas is highly dependent on the dispersal system, which require sophisticated engineering skills to develop.[438] Conversely, contagious agents could expose (and possibly infect) large numbers of people over a wide area through the ongoing outbreak and the movement of infected people without the need for a sophisticated dispersal device.

Insofar as an attack is desired to cause disruption for a long period of time, *B. anthracis* is also a good candidate because its spores can persist in buildings or in the soil for years. For instance, two and a half months were required to perform decontamination operations at the Landover

> Existing non-contagious agents are very good at causing mass casualties or contaminating a large area for a long period of time if dispersed from a very sophisticated device. Contagious agents could have similar consequences with very simplistic dispersal methods.

mail facility in the aftermath of the 2001 anthrax attacks.[439] Gruinard Island, the site of testing of anthrax weapons in the former UK offensive weapons program, was dangerously contaminated for decades after testing ceased.[440] The entire topsoil of the island had to be decontaminated before the site was considered safe for human occupation.[441] Although the biological properties of *B. anthracis* enable a weaponeer to deny access to a particular location for a long time after an attack, a population may simply avoid the contaminated area and remain safe. In contrast, a contagious agent prolongs the effect of an attack because the population itself carries the hazard, and, therefore, risk can be minimized only by reducing human contact.

8.4.3.1 Contagiousness as a Desirable Characteristic to Increase the Footprint of an Attack

From the analysis above, the acquisition of a contagious agent would enable a weaponeer to expand the footprint of their attack in terms of casualties, area, and time. Moreover, the fact that an outbreak can spread, sickening or killing victims beyond those infected by the initial attack, removes the requirement to produce a sophisticated dispersal device to cause a mass casualty attack. For this reason, contagious agents may be desirable by malicious actors who have significant skill in virology but no skill in machining/engineering to make a munition.

However, contagious agents have drawbacks—primarily that their affect is difficult to predict or control. Some state and sub-state groups may not desire an agent that could infect their soldiers or supportive populations, or could cause mass fatalities. For instance, the United States' now defunct offensive biological weapons program considered a potential agent's ability for human-to-human transmissibility as a negative characteristic.[442,443] This feature may be especially problematic if their supporters live primarily in low-income countries because global outbreaks there may be more severe than in high-income countries where the public health infrastructure is more robust. However, unlike the United States, the Soviet Union's program sought out highly contagious pathogens for at least some of the lethal pathogens in its arsenal.[444] At the state actor level, weaponeers may covertly stockpile a vaccine to mitigate friendly losses to their contagious agent.

If a contagious, lethal agent is desired by a weaponeer, they could choose to work with a wild type agent other than the influenza viruses or coronaviruses. Of the non-GoF Select Agents, smallpox virus, *Yersinia pestis*, and the filoviruses (Ebola and Marburg viruses) are the only viruses that have a high case fatality rate and are significantly contagious. *Y. pestis* causes pneumonic plague if inhaled by a victim. This pathogen is often described as being highly transmissible, with a historical R_0 at or above that for influenza strains.[445,446,447] However, these historical studies draw upon past outbreaks in areas that do not

mirror the modern US.[448,449] Indeed, most of the secondary cases of pneumonic plague described occurred in household members of the ill, who also were the primary caregivers at a time when hospitalization of the critically ill was still rare. Estimates of the R_0 of pneumonic plague in the modern United States suggest that an outbreak would extinguish rather rapidly.[450] Similarly, outbreaks of Ebola virus disease in Africa were associated with an R_0 that approached that of influenza or SARS.[451,452,453] However, much of the transmission was in makeshift healthcare facilities suggesting that the R_0 in the US would be much smaller.[454,455] Smallpox virus is held in just a few, highly secure locations throughout the world and, therefore, may be difficult for an adversary to acquire. That being said, an adversary able to leverage the information produced by GoF experiments may well be able to use non-GoF approaches to synthesize smallpox virus *de novo* using well described rescue systems for other orthopoxviruses.[456] Similarly, although there is no environmental reservoir of SARS-CoV, the significant transmissibility and lethality of the wild type strain may motivate a weaponeer to use reverse genetics to synthesize it or attempt to acquire it from a laboratory.

If a contagious, incapacitating agent is desirable, not many options to acquire such an agent are available. Wild type pandemic or seasonal influenza viruses are obviously highly contagious and incapacitating, however, residual immunity from past outbreaks may hamper the spread of these illnesses.[457,458] An adversary could choose a wild type strain that has not circulated in several decades to reduce the effect of residual immunity in the population. Alternatively, modified strains of many pathogens, including mumps virus and measles virus, which are already highly contagious, could be made to overcome protective immunity using techniques similar to those used in GoF experiments. However, these experiments would be associated with their own information risk and, therefore, are not explored further here.

> A contagious pathogen may be desirable by a scientifically trained adversary with minimal engineering skill or by a state. Smallpox virus and SARS-CoV are the only wild type pathogen that is deadly and as transmissible (or more) than influenza virus. Wild type influenza viruses are contagious, especially if a decades old strain is used to minimize the effect of residual immunity, and highly incapacitating.

8.4.3.2 Enhanced Growth as a Desirable Characteristic to Increase the Footprint of an Attack

Because pathogens are self-replicating, to increase the footprint of an attack, an adversary could simply grow more of the agent. This goal *could* be accomplished by increasing the volume of culture used or by increasing the viral titer in the culture. This rationale supports the consideration of enhanced growth of a pathogen in culture or eggs as a dual-use phenotype because an adversary can produce more pathogen with the same amount of resources if the pathogen can grow to a high titer. We therefore evaluated how producing more pathogen for a biological attack, in terms of the amount of pathogen released, relates to the footprint of the attack, particularly in terms of number of victims infected (data is provided in the FOUO addendum). The results show that, for small amounts of pathogen effectively released, the number of initial infections scales well with the amount of pathogen produced (that is, tenfold more pathogen released leads to tenfold more initial infections). For larger amounts of pathogen, the increase in casualties begins to taper off as the amount of pathogen released increases. Specifically, for every tenfold increase in pathogen released, the number of initial infections produced increases by only two- to three-fold or less. Our results show that increasing the growth of a wild type strain will have a limited effect on the amount of casualties produced even for actors who do not have access to industrial scale production facilities. In short, even relatively poorly growing pathogenic strains of influenza virus grow well enough such that producing more pathogen produces limiting returns for use in an attack.

Moreover, if a malicious actor wants to infect as many people as possible, spending the effort to modify a strain to become high growth is probably not worth the risk that its transmissibility would be decreased. By their nature, transmissible agents would increase the footprint of the attack, potentially by several orders of magnitude if an ongoing and global outbreak can be sparked. An attack that initially infects several thousand people will quickly grow out of local control (as demonstrated in the Risk Assessment of Accidents and Natural Disasters), and therefore, the number of casualties produced by the attack will depend on the pathogenicity and transmissibility of the pathogen in the context of a global epidemic and not the initial number infected. In Chapter 5, it is demonstrated that very few covert infections of the public are required to seed nearly guarantee that an outbreak would escape local control for the influenza viruses (ten or fewer), so the initial number of people exposed could be very small indeed.

> Experiments that enhance the growth in culture of the GoF pathogens are of minimal information risk because producing more agent results in few additional casualties.

8.4.3.3 Countermeasure Resistance and Evasion of Existing Immunity as Desirable Characteristics to Increase the Footprint of an Attack

The GoF phenotype of evasion to medical countermeasures includes the ability to evade the protection afforded by vaccines, antivirals, and diagnostics. The evasion of diagnostics is not particularly relevant to GoF diseases released intentionally. SARS and MERS diagnostics are used in the US only for people already thought to be infected with the disease based on their clinical symptoms.[459] Since no specific treatments for these diseases currently exists, these diagnostics would simply be used to direct public

[459] Centers for Disease Control and Prevention, (2014) "Middle East Respiratory Syndrome (CDC) - CDC Laboratory Testing for Middle East Respiratory Syndrome Coronavirus (MERS-CoV)," http://www.cdc.gov/coronavirus/mers/lab/lab-testing.html.

health measures.[460,461,462] Given the importance of quarantine and isolation in the control of coronavirus outbreaks, diagnostics could be used to direct public health resources to prevent the outbreak escaping local control.[463]

Because pandemic and seasonal influenza viruses are highly contagious, the evasion of diagnostics would have little consequence to the eventual extent of an outbreak, but may complicate the efficient use of antivirals by confounding the identification of patients who are infected with influenza. For strains of avian influenza modified to be contagious between humans, the evasion of a diagnostic would have just as few benefits to a malicious actor as it would for the use of a coronavirus.

In an intentional attack with influenza virus, evasion of immunity induced by vaccination is of little relevance because we presume the attack would be a surprise and the US would not have prepared sufficient stocks of a protective vaccine ahead of time. For this reason, several months would pass before the vaccine would be ready for deployment, at which time the disease would have spread globally (or, if poorly contagious, extinguished by itself). However, the vaccine could still be used to limit the casualties and temporal duration of the outbreak (see Figure 9.5 in Chapter 9 to see how the timing of the deployment of a vaccine affects global casualties). However, a virus that can overcome protective immunity induced by *any* vaccine would increase both the casualties of an attack and its duration. Because no approved vaccines for the coronaviruses currently exist, malicious actors have no need to make a strain of these viruses able overcome protective vaccination.

An actor wishing to leverage a recently circulating strain of influenza may desire to modify their strain to avoid protective immunity. Residual immunity in the population can significantly reduce the chance that an outbreak would escape local control and the consequences of an outbreak (Figures 6.35 and 6.57 in Chapter 6). However, avoidance of residual immunity can be obtained either through GoF methods or by the selection of a wild type strain that has not circulated recently. Infections by the SARS and MERS coronaviruses are sufficiently rare that an adversary has no need to create a strain that can evade residual immunity from a past infection.

Antiviral resistance of influenza viruses would be useful to an adversary to increase the casualties caused by an outbreak in the United States and to increase the chance that a local outbreak escapes local control (as shown in Figures 6.53 for seasonal influenza and 6.55 for pandemic influenza in Chapter 6). Given that the majority of the world does not have access to the amount of antivirals that the United States does, antiviral resistance has little influence on global consequences.

8.4.4 Gain of Function Strains Compared to Naturally Occurring Strains

8.4.4.1 A Non-Unique Information Risk Inheres in Experiments Describing the Creation of Highly Transmissible, Highly Deadly Strains of Pathogens

When compared to strains of pathogens created via the use of GoF research information, we find that naturally occurring strains generally are not both highly pathogenic and highly transmissible (with the exception of wild type SARS-CoV). Although SARS-CoV has an R value greater than one, the fact that the virus is transmissible only after symptoms present, the disease is largely spread within the medical system, and the long incubation period of the disease makes outbreaks of SARS-CoV relatively easy to control (as described in Chapter 4, past outbreaks have witnessed a two-fold drop in the R value of a SARS outbreak after control measures are implemented). Only smallpox virus, which exists only in a few laboratories, has a case fatality rate greater than 10% and is transmissible enough to cause a pandemic (an R value significantly greater than one in the context of a robust public health response). Because stocks of smallpox virus are tightly controlled, an adversary might turn to GoF studies to acquire a pathogen that is both highly pathogenic and highly transmissible. We note that no GoF study to date has conclusively produced strains with the combination of the desired phenotypes because of weaknesses of animal models in predicting pathogenesis in humans. Moreover, whether enhancement of a phenotype, like transmissibility, would be sufficient to achieve the traits desirable by a weaponeer for an attack on a human population remains unclear. That is, an experiment may show an increase in the transmissibility of a pathogen among ferrets, but this observation cannot be translated into a specific R_0 value in a human population (or if the increase is sufficient to obtain the desired weapon characteristics). With these limitations in mind, the following GoF results would be of concern:

- Seasonal/pandemic influenza virus that retains its transmissibility but is modified to have a case fatality rate greater than 10%,
- Avian influenza viruses that are modified to be as transmissible as seasonal influenza but retain their high fatality rate, and
- SARS/MERS-like CoV that is made more transmissible.

Scientific communications that detail the creation of strains with these traits would be of concern because they would provide a route to the acquisition of a pathogen as useful to a weaponeer as smallpox virus. Importantly, we have no data that speaks to the possibility that these phenotypes are achievable in the laboratory. Perhaps, due to the epidemiology of influenza and the coronaviruses, high mortality (in excess of that associated with the 1918 pandemic strain) and transmissibility are conflicting phenotypes because the very ill do not contact many others during the contagious phase of the illness outside of a hospital.[464] Moreover, these phenotypes will not emerge by chance in the laboratory. Any experiment that selects for one phenotype is likely to allow other phenotypes to drift. That is, experiments that focus on enhancing transmissibility alone are likely to arrive at viruses that are optimized for transmissibility. In those same experiments, the viruses obtained can drift to less pathogenic forms because selection for this trait is not maintained. In fact, this phenomenon was observed in the Fouchier experiment with H5N1, albeit not in the Sutton 2014 experiment with H7N1.[465,466] In contrast, experiments that do not involve selection but

[466] "The present findings show that adaptation of the H7N1 isolate does not appear to substantially decrease the virulence of the virus." In: Troy C. Sutton et al., "Airborne Transmission of Highly Pathogenic H7N1 Influenza Virus in Ferrets," *Journal of Virology* (2014): p. 6623-6635, http://www.ncbi.nlm.nih.gov/pmc/articles/PMC4054360/.

the systematic manipulation of the components of the virus, could lead to strains that have a variety of phenotypes that are enhanced compared to a parental strain. For example, influenza reassortment studies that choose one or two genomic segments from a highly transmissible influenza strain and switch them for the cognate segments from a highly pathogenic strain can result in a strain where both phenotypes are enhanced compared to the parents.[467]

Although some GoF studies could produce information of use to an adversary wishing to obtain highly transmissible, pathogenic agents, these studies are not the only means of acquiring this type of agent. Given that the sequence of smallpox virus is public, a technically sophisticated actor could use methods similar to those employed in GoF laboratories to synthesize all (or the unique parts) of the smallpox genome and use it to rescue live virus.[468] To support this effort, rescue systems are published already for the orthopoxviruses.[469]

Moreover, researchers could use pathogens not listed in the GoF framework, but manipulate the same traits considered in the framework to obtain highly transmissible and lethal strains of pathogens. Examples include:

- Strains of filoviruses or henipaviruses that retain their pathogenicity but are modified to be much more transmissible, and
- Strains of highly transmissible agents (like polio virus or measles virus—neither one of which is a select agent) that have been modified to become more deadly and/or overcome protective vaccination.

Finally, note that the reconstructed wild type strain of the 1957 influenza virus is predicted to be highly transmissible and significantly pathogenic, and methods to recreate this virus through reverse genetics are routine in influenza laboratories (as described in the Supplemental Information, 1918 influenza is less transmissible in the modern population due to the circulation of antigenically similar H1N1 strains). Similarly, the wild type strain of SARS-CoV is highly transmissible and significantly pathogenic as well (as described in Chapter 6, further enhancing the transmissibility of SARS-CoV increases the chance that a global outbreak would occur because of the susceptibility of outbreaks caused by the wild type virus to control measures). Therefore, GoF studies may be of use only if an adversary wishes to obtain a strain that is *more* pathogenic than that the 1957 pandemic influenza strain or more transmissible than SARS-CoV.

8.4.4.2 A Non-Unique Information Risk Inheres in the Experiments Describing the Creation of Highly Transmissible Strains of Influenza Virus with Specific Enhancements in Morbidity

Wild type influenza strains are well-suited for use as incapacitating agents because they have a small mean infectious dose and cause a debilitating illness with a short incubation time. However, unlike other pathogens researched in offensive weapons programs, influenza does not cause a particularly long lasting or chronic illness. For this reason, a strain of influenza that produces a much more protracted course of illness or chronic illness would provide an advantage over naturally occurring strains because no naturally occurring strain with this combination of phenotypes is known to exist.

468 Institute of Medicine (US), Committee on the Assessment of Future Scientific Needs for Variola Virus, "Live Variola Virus: Considerations for Continuing Research," p. 13, 132.

469 An example of a publication of a rescue system for the orthopoxviruses is given in the FOUO appendix.

As above, GoF research is not a unique pathway to obtain this type of dual-use information. For example, an adversary could produce strains of mumps, polio, or measles that can overcome protective vaccination, to obtain an agent with significant morbidity and even greater contagiousness than is currently possible with influenza virus. Moreover, the experimental means to produce viral strains that can overcome vaccination is well established. As such, this method of obtaining a highly-contagious, incapacitating agent requires relatively little "research". In contrast, the mechanisms underlying the nature of pathogenicity of influenza, and what leads to a protracted illness, are still unknown. Moreover, no research has pointed to any mechanism for chronic influenza infection and the creation of such a strain would require a long-term research effort.

8.4.4.3 Evasion of Medical Countermeasures is a Possible Future Information Risk

Evasion of medical countermeasures is a phenotype with minimal information risk today. Because no medical countermeasures for the coronaviruses are in use today, there is no need to produce a strain of these pathogens that can evade notional countermeasures. For the influenza viruses, vaccines, antivirals and diagnostics are all in use. Because an influenza virus used in an attack would only serendipitously match the seasonal vaccine produced and stockpiled by any nation, several months would pass between the time an attack occurs and the time that a vaccine is even relevant to control the outbreak. After that point, a vaccine has some utility for preventing mortality and morbidity and curtailing the outbreak (by increasing the number of contacts needed to spread the disease). But, as shown in our Biosafety Risk Assessment (Chapter 6) the evasion of vaccine-induced immunity at best provides a modest increase in total mortality.

Similarly, when considering the mortality caused in a global outbreak, at best, antivirals reduce the death rate of influenza by a few fold. However, in the US, because of our significant supplies of antivirals, deaths can be greatly reduced by their effective administration. Conversely, then, an antiviral resistant strain could increase the deaths from an attack with influenza virus in the US.

Diagnostics are currently used to direct the use of antivirals, which either are not plentiful enough globally to influence consequences significantly or are so plentiful as to not be limiting in the US. Diagnostics are also used to identify that an outbreak with a novel virus is occurring in the first place.

If an adversary wishes to use a wild type influenza strain in an attack, residual immunity from previous outbreaks may limit the footprint of the attack. However, an adversary could simply use a wild type influenza virus of a serotype that has not circulated recently to avoid this shortcoming. Once again, published sequence information, combined with well-established protocols for the rescue of influenza viruses, could be used to obtain these strains.

However, as vaccine technology advances, research on the evasion of medical countermeasures COULD become an information risk. For example, once a universal influenza vaccine is developed, the evasion of immunity induced by this vaccine may be critical for an adversary to cause an outbreak using influenza virus as a weapon. Studies in other pathogens have described the development of strains able to overcome protective vaccination due to the expression of exogenous genes (and not via escaping immune recognition). Similarly, once systems are in place to develop a vaccine against a newly identified serotype of influenza virus in a few weeks instead of a few months, evasion of induced immunity becomes more useful to an adversary. Likewise, if antivirals become more widely available globally, research on the evasion of that antiviral would pose an information risk. Clearly, as highly effective medical countermeasures for the coronaviruses are developed, studies on their evasion would pose an information risk. That being said, since these medical countermeasures do not yet exist, designing an experiment to evade them is not currently possible. None of these technologies are likely to be deployed in the next five

years. However, once information is published, it is permanently available and retains its utility far into the future. For this reason, the information risk relevant to the evasion of medical countermeasures should be continually re-evaluated.

8.4.4.4 Enhanced Growth in Culture Affords Little Information Risk

As described in Section 8.4.3.2, strains with enhanced growth *in vitro* or *in ovo* can be used to produce more agent to disperse from a weapon using the same amount of resources. However, even poorly growing pathogenic strains can be grown in enough quantity with commonplace equipment to obviate the growth of more to produce more casualties. In contrast, the use of contagious agents, by their nature, increases the footprint (in terms of area affected and illnesses) by many orders of magnitude. For this reason, publications on changes in this phenotype present very little information risk simply because the GoF pathogens are contagious.

8.4.4.5 Summary of Possible Comparative Information Risk Arising from GoF Studies

Figure 8.2, below, provides an overview of the potential information risk of GoF research.

Dual-Use GoF Phenotype	Seasonal/Pandemic Influenza	Avian Influenza	Coronaviruses
Enhanced transmissibility in mammals			
Enhanced pathogenicity in mammals			
Enhanced transmissibility while maintaining pathogenicity			
Overcoming natural or induced immunity			
Evading diagnostics			
Antiviral resistance			
Enhanced production in cell culture or eggs			

Figure 8.2. Possible information risk arising from dual-use information relevant to GoF research. White denotes that no significant information risk exists. Dark shading denotes a significant information risk, albeit a risk that is not unique to GoF research. No information risks unique to GoF research were found.

8.5 Overview of the State of the Science of Dual Use GoF Information

In this section, we discuss how the existing body of GoF research already describes methods to obtain strains of influenza- and coronaviruses with GoF traits, regardless of their true utility to a weaponeer. We synthesize these two pieces of information to arrive at our final conclusions. That is, this section describes the GoF information risk already realized through the previous publication of dual use information. To maintain this discussion at the full-and-open level we have not cited the specific papers at issue and have instead provided these in an appendix at the For Official Use Only level. Here, we simply characterize the state of the science and describe the seminal publications.

We first describe the state of the science for research on influenza and later describe the state of the science for the coronaviruses. We discuss each GoF phenotype in turn. Most scientific publications investigate morbidity and mortality simultaneously, characterizing disease outcomes such as weight loss

or fever alongside death of the animals. For this reason, we discuss morbidity and mortality jointly as the characteristic of pathogenicity.

8.5.1 State of the Science of GoF Experiments in Influenza Viruses

8.5.1.1 Enhanced Transmissibility in Mammals

Some research groups focus on understanding the factors that cause some H1N1 strains (such as the 2009 pandemic strain or 1918 pandemic strain) to be highly transmissible while other H1N1 strains (such as avian strains and the Puerto Rico 8 strain) to not transmit in mammals. These groups use a variety of methods to develop transmissible strains of H1N1 viruses, including:

- Simple reassortment, and
- Identification of mutations unique to transmissible strains followed by the use of reverse genetics to introduce these changes in a non-transmissible strain.

These experiments, while demonstrating the ability to increase the transmissibility of influenza viruses, are of limited dual utility because one of the parental strains already has the traits desired by a weaponeer (transmissibility and pathogenicity). These experiments were executed to determine what factors are sufficient to cause a poorly pathogenic virus into a highly pathogenic virus. An adversary gains no advantage using one of these modified strains compared to the parental, pathogenic strain.

In contrast, in experiments dealing with avian-origin viruses, the parental strains are either highly lethal OR highly transmissible in mammals and the manipulations described are required to obtain a strain that is lethal AND transmissible in mammals. Several papers describe methods to manipulate highly pathogenic strains of avian influenza from the H5, H7 or H9 subtype to arrive at a strain that is transmissible by droplets in mammals (typically ferrets or guinea pigs). These studies use a variety of methods including:

- Simple serial passaging in ferrets,
- Directed, sequential reassortment of an avian strain with a pandemic strain,
- Directed reassortment followed by serial passaging,
- Targeted mutagenesis followed by serial passaging, and
- Mutagenesis of HA, followed by selection based on its binding properties and the creation of a chimeric virus.

Some of these experiments require only minimal skill in virology. The serial passaging experiment could be repeated by an actor with limited skills in molecular biology to obtain a strain of avian influenza that is transmissible in mammals. For actors with significant skill in molecular biology, these transmissible, avian-origin influenza viruses could be synthesized using reverse genetics (a common practice in GoF laboratories) because all investigators have published enough information on the specific molecular changes observed in the avian-origin strains that are transmissible in mammals. Specifically, in the case where serial passaging was used, the mutations acquired by the strains of interest were published. In the case of the reassortment study, the gene segments that contributed to the transmissible strains from both parental strain were published. For this reason, to leverage the information in these studies, an actor need not repeat the experiments exactly, but simply reconstruct the viruses that the authors identified.

The abundance of literature describing the creation of avian-origin strains that are transmissible in mammals indicates that the GoF information risk for enhanced transmissibility of influenza viruses is

already realized. Further publication on this topic would likely not exacerbate this risk because existing published methods are relatively simple to replicate.

Any study, such as ours, that examines the existing literature on transmissibility of influenza viruses to determine the dual-utility of the resulting information suffers from a critical shortcoming. The published studies use too few animals in transmissibility experiments to understand exactly *how transmissible* these newly developed strains are. That is, none of these studies compared the transmissibility of these strains in a sufficient number of animals so that levels of transmissibility (compared to wild type seasonal or pandemic influenza strains) could be determined. Moreover, ferrets in isolators do not interact with each other the same way that people in a city do. For this reason, it is impossible to use laboratory experiments to conclusively determine if the increase in transmissibility observed translates to a dangerous R_0 value, which is determined retrospectively by scrutinizing human epidemiological data. This distinction is important because risk of an outbreak escaping local control and the risk of a resulting outbreak both increase significantly as an influenza virus approaches a transmissibility comparable to that of a seasonal influenza strain (see Chapter 6). Possibly all of these viruses may be somewhat transmissible, but in a human population their R_0 may be much less than one, which is the value required to cause a global epidemic.

Experiments to compare the transmissibility of wild type strains of seasonal and pandemic strains to modified strains would help determine if information risk inheres in further publications of strains that have been modified to become transmissible. If these modified strains are in fact transmissible, but much less so than seasonal or pandemic strains, then a remaining information risk would exist in further experiments that *could* identify a strain that is as transmissible as seasonal or pandemic strains.

> Several groups have published simple methods to increase the transmissibility in mammals of pathogenic strains that were previously transmissible only in avians—therefore this type of information risk is already realized

8.5.1.2 Enhanced Pathogenicity

Several papers describe virulence factors necessary for the maintenance of pathogenicity in highly pathogenic strains of influenza, such as the avian influenza and 1918 pandemic influenza viruses. Typically, these researchers identify mutations unique to the highly pathogenic strains and introduce these mutations into a less-pathogenic strain using reverse genetics. In a few experiments, researchers used pathogenic strains that were isolated from patients with severe illness, attempting to determine what characteristics made the strains infecting these patients even more pathogenic than the parental strain. Other researchers use reassortment between highly pathogenic and non-pathogenic strains to obtain a chimeric virus to identify the components of the pathogenic strain minimally necessary to confer pathogenicity into the non-pathogenic background. These experiments, while demonstrating the ability to increase the pathogenicity of influenza viruses, are of limited dual utility because one of the parental strains already has the traits desired by a weaponeer (transmissibility and pathogenicity). If an adversary has the pathogenic, transmissible strain, they gain no advantage from these manipulations.

In contrast, other experiments result in strains that are MORE pathogenic than any parental strain used. A variety of methods are used to enhance the pathogenicity of influenza viruses, including:

- Random reassortment of seasonal and pandemic H1N1 strains,
- Directed, serial reassortment of an avian-origin strain with a pandemic strain,

- Site directed mutagenesis of residues associated with increased virulence in other strains to increase the virulence of an avian strain, and
- Serial passaging in mice.

Although the serial passaging studies require minimal skill in molecular biology, they are also of marginal dual-utility due to the limitations of the mouse model system of predicting pathogenicity of a strain in humans (or ferrets).[470] That said, these experiments indicate that an adversary seeking to develop a more pathogenic virus could serially passage their strains in ferrets (or humans) to obtain a virus that is more pathogenic. However, sometimes these serial passaging experiments lead to less pathogenic strains.

For actors with significant skill in molecular biology, strains with enhanced pathogenicity could be synthesized using reverse genetics (a common practice in GoF laboratories) because all investigators have published the specific molecular changes observed in the strains with enhanced pathogenicity. For this reason, to leverage the information in these studies, an actor need not repeat the experiments exactly, but simply reconstruct the viruses that they have identified.

> Several groups have published methods that require skills in molecular biology to increase the pathogenicity of influenza virus strains—therefore this type of information risk is already realized. But a small remaining risk exists from the publication of simple methods to the same result. Another modest risk inheres in the publication of methods to modify influenza viruses to cause chronic illness.

The abundance of literature describing the creation of influenza virus strains with enhanced pathogenicity indicates that the GoF information risk for this trait is already realized. However, leveraging this information requires skill in molecular biology (specifically, reverse genetics), the appropriate facilities and equipment. The publication of simple selection methods supporting the conclusion that virulence could be increased in relevant animal models via this simple method poses a remaining information risk. In contrast, we found no publications describing the creation of an influenza virus strain that can produce prolonged or chronic illness, which is important in the context of malicious actors seeking to produce an incapacitating agent.

8.5.1.3 Enhanced Transmissibility While Maintaining/Enhancing Pathogenicity

Experiments in this category are of particular concern because they could enable a hostile actor to obtain a strain that has a combination of pathogenicity and transmissibility that surpasses all wild type, human pathogens except for smallpox virus. Several papers describe methods to manipulate highly pathogenic strains of avian influenza from the H5 or H7 subtype to arrive at a strain that is transmissible in mammals (typically ferrets). Many of these studies also test the resulting strains for pathogenicity. The studies of interest here use a variety of methods including:

- Simple serial passaging in ferrets, and
- Directed, sequential reassortment of an avian-origin strain with a pandemic strain.

In the serial passaging experiment, the researchers claim that no loss of pathogenicity is observed compared to the highly pathogenic parental strain after ten passages in ferrets. However, too few animals were used to assess pathogenicity to detect some loss of pathogenicity. In the reassortment study, the authors show that two of the four transmissible strains they identified are *more* pathogenic than either

[470] For example, Natalia A. Ilyushina et al., "Adaptation of Pandemic H1N1 Influenza Viruses in Mice," *Journal of Virology* 84 no. 17 (September 2010): 8607-8616.

parental strain (although they tested this phenotype in mice). Although the authors make this claim, their experimental design may not have been sufficient to detect true differences in pathogenicity from the parental strain relevant to humans.

The serial passaging experiment could be repeated by an actor with limited skills in molecular biology to obtain a strain of avian influenza that is newly transmissible in mammals and highly pathogenic (albeit this actor would need animals and the facilities to contain them). Moreover, all investigators characterized the resulting strains and published enough information (in the initial or follow-on papers) so that the strain of the desired characteristics could be directly produced by reverse genetic methods. Specifically, in the case where serial passaging was used, the mutations acquired by the strains of interest were published. In the case of the reassortment study, the gene segments that contributed to the transmissible strains from both parental strains were published.

For this reason, the GoF information risk for enhanced transmissibility while maintaining pathogenicity of influenza viruses is already realized. Further publication on this topic would likely not exacerbate this risk because existing published methods are relatively simple to replicate. Actors skilled in reverse genetics could instead recreate the strains with the desired traits that these groups characterized.

> Two groups have published simple methods to increase the transmissibility in mammals of pathogenic strains of influenza that were previously transmissible only in avians while maintaining (or enhancing) pathogenicity. Therefore, this type of information risk is already realized.

As discussed in the enhanced transmissibility section above, our retrospective study of the literature cannot conclusively determine the dual utility of these publications. Further studies with more relevant model animals would provide useful information about whether the resulting strains are likely to be both more pathogenic and highly transmissible in humans. Also, our study (and any animal study) is unlikely to conclusively determine if a transmissible strain would be similarly transmissible to seasonal influenza in human populations.

8.5.1.4 Overcoming Natural or Induced Immunity

As discussed above, the evasion of immunity is a desirable trait for a malicious actor if they wish to use a strain of influenza that recently circulated (and, therefore, need to overcome the significant residual immunity that exists in the population). For this reason, the information risk related to the ability of a modified strain to overcome natural or induced immunity inheres in the *methods* to foster an antigenic change in any desired virus strain. Therefore, methods published using attenuated strains are still relevant to this information risk. All of the published papers reviewed in this study focus on elucidating the mechanisms by which new strains with different antigenic profiles evolve. The methods involved include:

- Identification of unique changes between a parental strain and an antigenically distinct strain, followed by the introduction of these unique changes into the parental strain by reverse genetics,
- Serial passaging in cells in the presence of neutralizing antibodies, and
- Serial passaging in immunized animals.

The serial passaging experiments could be repeated by an actor with limited skills in molecular biology to obtain an antigenically distinct strain of influenza. Although one of the studies resulted in antigenically distinct strains that are as pathogenic (or even more so, in mice) than the parental stains, other studies that

use large numbers of passages create significantly attenuated strains and still others do not characterize the pathogenicity of their strains (however, fitness was assessed and maintained). Some studies using reverse genetics produce strains that are antigenically distinct and pathogenic. No matter which method was used, all investigators in the reviewed studies characterized the resulting strains and published enough information (in the initial or follow-on papers) so that the strain with the desired characteristics (distinct antigenicity and pathogenicity) could be directly produced by reverse genetic methods by a malicious actor with significant skill in molecular biology.

For this reason, the GoF information risk for creating strains of influenza that are antigenically distinct from their parental strain is already realized. Further publication on this topic would likely not exacerbate this risk because existing published methods are relatively simple to replicate.

> Several groups have published simple methods to create antigenically distinct strains of influenza virus. Therefore this type of information risk is already realized. To our knowledge, no one has published methods to create strains of influenza virus able to overcome the protection afforded by vaccination in general, which poses a remaining information risk.

No papers were found that describe the development of influenza strains able to overcome protective immunity without creating an antigenically distinct virus. Methods have been published describing the use of other pathogens (viruses and bacteria) expressing exogenous factors to create strains that enable the pathogen to kill infected hosts despite being effectively immunized with a vaccine matched to the serotype of the pathogen. However, these pathogens have larger and more plastic genomes than the influenza viruses and therefore, the development of such a strain of influenza would be a major research undertaking. Moreover, the benefits of this type of research would be highly suspect. Regardless of the reasons not to perform this research, the publication of methods to produce strains of influenza able to overcome immunity regardless of its serotype would pose an information risk.

8.5.1.5 Evasion of Diagnostics

Current generation influenza diagnostics function either via the recognition of epitopes in the virus (or antibodies to these antigens generated by a patient) or via recognition of unique sequences in the genome of the virus. Diagnostics that function by leveraging antibodies could be evaded in much the same way that host immunity can be evaded, so this possibility will not be discussed further.

No papers reviewed in this study discussed the production of strains of influenza that can evade diagnosis by the alteration of its genetic makeup (except for changes in the genome that lead to changes in antigens). Actors with skills in molecular biology (and knowledge of the genetic targets of the assays) could create strains of viruses with a series of silent mutations (mutations that alter the genomic material but do not change the encoded proteins) to confound recognition. However, codon usage in viruses is sometimes tightly linked to fitness (or other desired traits), and therefore, a malicious actor must test their new strains to ensure that all desired phenotypes were not lost. In any case, the publication of methods that demonstrate how to evade diagnostics via the alteration of the genome pose a remaining information risk.[471]

> Several groups have published simple methods to create antigenically distinct strains of influenza virus which can evade diagnostics that use the antigenic properties of the virus. Therefore, this type of information risk has already been realized. No methods have been published describing the modification of influenza strains to evade diagnostic methods reliant on unique genomic signatures. Therefore, this type of information risk remains.

[471] Wong E, et al. (2010) "Codon usage bias and the evolution of influenza A viruses," *BMC Evolutionary Biology* 10, 253

8.5.1.6 Antiviral Resistance

Because the creation of antimicrobial resistant strains is part of the drug-development process and part of risk assessment process for determining when the effectiveness of antimicrobials may expire, several publications on the creation of influenza strains resistant to antivirals could be found. The methods used involved:

- Identification of unique changes between a parental strain and a drug resistant strain, followed by the introduction of these unique changes into the parental strain by reverse genetics.
- Serial passaging in cells in the presence of low concentrations of the antiviral, and
- Infection of animals treated with sub-optimal concentrations of the antiviral.

Serial passaging and *in vivo* experiments could be repeated by an actor with limited skills in molecular biology to obtain an antiviral-resistant strain of influenza. *In vivo* methods also simultaneously select for fitness (and in some cases, pathogenicity), suggesting that the resulting strains might still be useful in a weapon. Studies using reverse genetics produce strains with several mutations, some of which lead to antiviral resistance and others compensate for the defects in pathogenicity or fitness caused by the primary mutation. These investigators characterized the resulting strains and published enough information so that the strain with the desired characteristics (antiviral resistance and pathogenicity) could be directly produced by reverse genetic methods by a malicious actor with significant skill in molecular biology.

For this reason, the GoF information risk for creating strains of influenza that are antiviral resistant is already realized. Further publication on this topic would likely not exacerbate this risk because existing published methods are relatively simple to replicate.

> Several groups have published simple methods to create antiviral resistant strains of influenza. Therefore this type of information risk is already realized.

8.5.1.7 Increased Production in Cell Culture or Eggs

The vast majority of studies identified in which the production of viruses in cell culture or eggs was enhanced involved the introduction of some components of pathogenic strains into attenuated strains. These studies were designed to create attenuated strains with the immunoreactive antigens of the pathogenic strains suitable for use as vaccines. Several studies discuss the generation of strains with enhanced growth properties by reassorting pathogenic influenza viruses with attenuated strains adapted for growth in eggs or culture.[472] However, these strains were chosen because they simply express the HA and NA antigens in a virus suitable for vaccination.

Others have adapted attenuated strains to achieve a 100-fold increase in titer after growth in cell culture by serial passaging, but this method is likely to allow pathogenicity and transmissibility to drift.[473] Others

[472] Zhang W et al. (2011) "Increase in viral yield in eggs and MDCK cells of reassortant H5N1 vaccine candidate viruses caused by insertion of 38 amino acids into the NA stalk," *Vaccine* 29, vol 45: 8032-41.

[473] For example: Murakami S., Horimoto T., Ito M., Takano R., Katsura H., Shimojima M., Kawaoka Y., "Enhanced growth of influenza vaccine seed viruses in vero cells mediated by broadening the optimal pH range for virus membrane fusion," *Journal of Virology* 86 (2012): 1405-1410.

have used random mutagenesis of the HA gene to identify high growth mutants, but these mutants are likely to be poorly pathogenic.[474]

In contrast to these studies, other researchers have serendipitously found that some pathogenic strains demonstrate increased growth in cells or eggs using a variety of methods, including:

- Serial passaging in animals, and
- Identification of unique changes between a parental strain and a highly pathogenic strain, followed by the introduction of these unique changes into the parental strain by reverse genetics

The researchers leveraging reverse genetics introduced changes found in a highly pathogenic strain into a less pathogenic background to determine if these changes were sufficient to increase pathogenicity. They serendipitously, but perhaps not surprisingly, found that the growth of these pathogenic virus strains in culture or *in vivo* was enhanced. Since a malicious actor would likely desire this combination of phenotypes, this type of study generates biosecurity information risk. However, beyond using reverse genetics to synthesize these strains, these pathogenic, high-titer strains could be directly acquired from clinical samples.

> Several groups have published approaches of developing highly pathogenic strains of influenza that grow to a higher titer than their parental strains. Repeating these experiments requires skills in molecular biology. Those without molecular biology skills could repeat a serial passaging experiment, but they must take measures to retain pathogenicity of the final strain. For these reasons, little information risk remains for this trait.

Actors unable to acquire the specific highly pathogenic strains studied and who lack skills in molecular biology skill could instead repeat one of the serial passaging studies published. However, both of these studies used mice as their model system to identify strains that were more pathogenic and grew to a higher titer in cell culture or in eggs. Because of the weakness of the mouse animal model, passaging in mice may not lead to strains that are pathogenic in people. Presumably, passaging the virus in another animal model would retain the virulence of the strain (as shown in the passaging experiments above) and may result in higher growth variants.

8.5.2 State of the Science of GoF Experiments in the Coronaviruses

8.5.2.1 Enhanced Transmissibility in Mammals

No model system currently exists for the study of transmissibility of SARS- or MERS-CoV and, therefore, no studies have described methods to increase the transmissibility of these viruses. Therefore a significant information risk remains for any studies that describe the development of an animal model of transmission. However, these studies are necessary to understand the evolution of the viruses, their life cycle, their associated pathology, and pathways for developing vaccines and drugs.

[474] Ye J. et al. (2015) "Error-prone pcr-based mutagenesis strategy for rapidly generating high-yield influenza vaccine candidates," *Virology* 482: 234-243.

8.5.2.2 Enhanced Pathogenicity

SARS- and MERS-CoV do not normally infect mice, so the virus must be manipulated to infect this host to study pathogenicity. In fact, mouse-adapted SARS-CoV cannot effectively bind to or infect human cells. For this reason, although several groups described strains of coronaviruses that have enhanced pathogenicity compared to the parental, mouse-adapted coronavirus strains, these viruses are presumably acting in mice more like the wild type SARS- and MERS-CoV do in humans. These experiments are performed to learn how SARS- and MERS-CoV became pathogenic to humans and not to determine how they could become more pathogenic in the future. If new experimental systems were developed, an information risk would be possible. That being said, even if these experiments were to be conducted, very little room for the enhancement of pathogenicity is possible due to the high case-fatality rate and severity of the symptoms of the diseases these pathogens cause.

> Model animal systems for the study of SARS- or MERS-CoV can give us information on how these pathogens became dangerous to humans but probably not how they can become more dangerous. If new experimental systems were developed, an information risk would be possible.

8.5.2.3 Enhanced Transmissibility While Maintaining/Enhancing Pathogenicity

Currently, no model system for the study of transmissibility of SARS- or MERS-CoV exists and, therefore, no studies have described methods to increase the transmissibility of these viruses. Therefore a significant information risk remains.

8.5.2.4 Evading Diagnostics

Current generation coronavirus diagnostics function either via the recognition of epitopes in the virus (or antibodies generated against these antigens by a patient) or via recognition of unique sequences in the genome of the virus. Diagnostics that function by leveraging antibodies could be evaded in much the same way that host immunity can be evaded. We found two papers that describe the selection of a SARS-CoV that can escape binding by antibodies. In these papers, researchers serially passaged the virus in cells in the presence of antibodies derived from infected patients. In one study, the researchers studied how pathogenic the escape mutants were and found that some retained their pathogenicity.

No papers reviewed described the production of strains of coronaviruses that can evade diagnosis by the alteration of its genetic makeup (except for changes in the genome that lead to changes in antigens). Actors with skills in molecular biology (and knowledge of the targets of the assays) could create strains of viruses with a series of silent mutations (mutations that alter the genomic material but do not change the encoded proteins) to confound recognition. However, codon usage in viruses is sometimes tightly linked to fitness (or other desired traits).[475] For this reason, a malicious actor must test their new strains to ensure that the desired phenotypes were not lost. The publication of methods that demonstrate how to evade diagnostics via the alteration of the viral genome pose a remaining information risk.

> We found two groups that have published simple methods to create antigenically distinct strains of SARS-CoV which can evade diagnostics that use the antigenic properties of the virus. Therefore, this type of information risk has already been realized. No methods have been published describing the modification of coronavirus strains to evade diagnostic methods that target genomic sequence. Therefore, this type of information risk remains.

[475] Gu W. et al. (2004) "Analysis of synonymous codon usage in SARS Coronavirus and other viruses in the Nidovirales." *Virus Research* 101, vol 2: 155-161.

8.5.2.5 Overcoming Countermeasures and Immunity

As no approved vaccines or antivirals exist for prevention or treatment of infections caused by the coronaviruses, experiments of this type are not possible so they pose no information risk. Moreover, methods to evade antibody-based countermeasures and small molecule countermeasures are well established for other pathogens, including influenza. If such countermeasures were developed in the future, an adversary is likely able to leverage any of these methods to develop strains of the coronaviruses that are resistant to the countermeasures.

Moreover, infections by the SARS and MERS coronaviruses are sufficiently rare so that an adversary has no need to create a strain that can evade residual immunity from past infections.

8.5.2.6 Increased Production in Cell Culture or Eggs

We found no papers describing the enhancement of viral growth in culture or eggs. However, SARS- and MERS-CoV grow to a relatively high titer in culture, suggesting enhancement of this trait is unnecessary.

8.5.3 Overview of the State of the Science of GoF Experiments

Figure 8.3, below summarizes the analysis of the literature already published relevant to GoF research. We found that much of the dual-use information that could arise from GoF experiments has already been published for the influenza viruses. For this reason, much of the information risk for this pathogen has already been realized. The remaining information risk inheres in the creation of simpler experimental approaches to the development of strains with enhanced pathogenicity or enhanced growth, and any method that leads to the creation of strains that can avoid protection by *any* vaccine or the evasion of diagnostics via alteration of its genome. In contrast, the lack of model animal systems for the study of transmission or enhanced pathogenicity of the coronaviruses leaves a significant information risk if these systems were developed. That is, future experiments that describe how to make a strain of the coronaviruses more contagious (or more deadly) have a significant information risk. Although medical countermeasures for the coronaviruses do not yet exist, if they were developed a malicious actor could easily leverage simple experimental procedures published for other pathogens to create strains that overcome the countermeasures.

Dual-Use GoF Phenotype	Influenza	Coronaviruses
Enhanced transmissibility in mammals		
Enhanced pathogenicity in mammals	Published methods require skills in molecular biology. No publications exist on creation of influenza strains that lead to chronic illness.	
Enhanced transmissibility while maintaining pathogenicity		
Overcoming natural or induced immunity	Via the creation of antigenically distinct strains only	N/A
Evading diagnostics	Evasion of immunological diagnostics only	Evasion of immunological diagnostics only
Antiviral resistance		N/A
Enhanced production in cell culture or eggs	Published methods require skills in molecular biology.	N/A

Figure 8.3. Status of the publication of potentially dual-use information relevant to GoF research. White denotes that no significant information risk is left either because the relevant information has already been published or the resulting trait is not dual-use. Dark shading denotes a lack of publications on the topic so a significant information risk may remain. Grey denotes that some information risk may be remaining.

8.6 Evaluation of the Capability and Intent of Malicious Actors to Leverage Dual Use Information

Given the analysis above, non-unique information risk resides in the ability to create strains of highly-transmissible, antiviral resistant pathogens that have a high case fatality rate and are not limited by residual immunity brought about by the natural circulation of similar strains. That being said, this risk is already realized because the methods to produce these strains is already published. For malicious actors interested in developing a uniquely capable incapacitating agent, research on the development of influenza strains that produce chronic or long-lasting illness would be of interest.

We acknowledge that GoF research is just one means through which a malicious actor may obtain such a pathogen. By leveraging GoF information, sophisticated actors could use reverse genetics to create a strain that was previously described by other researchers with all desired characteristics. Actors with limited skills in molecular biology could use the selection experiments described in the literature to attain strains that may have all the desired traits, but extensive testing would be necessary to identify a strain with all such characteristics. This section describes the actors with the capability and motivation to seek to leverage this information.

State actors, who in the past have sought deadly strains and incapacitating strains of pathogens for use in offensive weapons programs, clearly often have the ability to acquire the equipment and expertise to use reverse genetics to create any strain of influenza or coronavirus described in the literature. Moreover, states likely would have the ability to design and produce a cache of vaccines (in the case of modified influenza viruses) that could protect their own population from the contagion that may spread from their intended target (and to protect their workers during the development and weaponization process). For this reason, if states were to leverage GoF information for malicious use, they would likely target information

on the influenza viruses (instead of the coronaviruses) and would be uninterested in strains that can avoid any type of vaccine protection. That being said, secrecy inside a state program may hamper the coordination of the offensive and defensive components of a biological weapons program. For example, those working on countermeasures in the Soviet biological weapons program lacked the clearance to know about the offensive side.[476,477] Moreover, the stockpiling of vaccines specific to a strain of influenza virus that has no risk of a natural outbreak could undesirably broadcast information about a state's offensive program.

Other malicious actors, from individuals to terrorist groups, have so far shown very little ability to acquire or grow biological agents. The few terrorist groups that have attempted to do so have relied on bacterial agents, not viral agents. The publically available literature suggests that no sub-state group has so far demonstrated the scientific sophistication and the resources necessary to leverage GoF information for malicious purposes.

In theory, a lone outsider (or small group of outsiders) with scientific training may have the ability to perform the manipulations necessary to obtain modified pathogens via relatively simple methods. Alternatively, if unconstrained by time and resources these technically trained actors may be able to use reverse genetics to obtain any desired strain. Industry standards for customer and sequence screening, in part supported by US government guidance, may prevent actors from acquiring synthesized pathogens via genetic material synthesized by industry. However, some gene synthesis (domestically and internationally) companies do not voluntarily follow the industry standards or US government guidance.

Lone scientific actors working in GoF laboratories (i.e., insiders) can simply directly acquire the desired strains as described in Chapter 7, above. Given the access controls implemented in containment laboratory, there is little opportunity for an insider to carry out a clandestine development and testing program inside the laboratory they legitimately have access to. Therefore, insiders are not considered a driver of information risk because they have access to strains and unpublished data.

A malicious actor developing an engineered strain would presumably need the resources to test the newly developed strain to ensure that it has all the traits desired. Animal testing facilities are expensive and difficult to covertly obtain, establish and operate without running the risk of self-infection and/or exposing the public. Sub-state groups, however, are likely to be satisfied with more rudimentary animal testing than those conducted by scientists seeking to publish in a peer-reviewed publication.[478]

> Of the potential malicious actors, only state actors have the resources, technical sophistication and motivation to leverage dual-use information arising from GoF studies. These states could protect their own population by secretly stockpiling an effective vaccine against their modified agent, suggesting they may prefer to target influenza viruses over the coronaviruses.

If somehow a scientific actor can create a facility that is sufficiently remote to develop the strains and perform the needed testing without being noticed (by intelligence gathering or by causing an outbreak), they could produce a highly contagious, highly lethal strain of virus. These properties avoid an often noted shortcoming of small groups wishing to produce an effective biological weapon: that they lack either the scientific expertise to create a useful biological agent or the engineering expertise to create a useful biological munition (both of which are normally needed to create a weapon capable of inflicting

mass casualties). Infections caused by rudimentary devices (like a spray bottle) may be enough to seed a global pandemic causing mass casualties. However, as noted in Chapter 7, above, we know of no lone actor who has ever desired to cause a global pandemic (albeit, a small group, R.I.S.E, did). Moreover, terrorist organizations and individuals appear to act more on the emotional and societal motivations towards radicalization and violence, suggesting a greater focus on the immediate, rather than long-term, response or outcome of an act.[479] Of course, historical examples do exist of individuals and terrorist groups that invested significant resources and time in planning of an attack (see Section 7). Whether the calculus of long-term illness or mass casualty through infection is attractive to sub-state actors is not known from publicly available literature.

One final caveat: the unsophisticated actor today could leverage advancing technologies to gain a significant body of skills and knowledge. Software is being developed to automate the research process, with the possible outcomes of increasing reproducibility and decreasing human involvement in the experimental process.[480] Finally, several online blogs, websites, video journals, and analytic technologies increasingly are being used to identify experimental protocols, troubleshoot experimental problems, and design experimental reagents such as DNA primers for polymerase chain reaction experiments.[481] Together, these changes may increase democratization of life sciences experiments and lower the level of skill and advanced scientific knowledge needed to conduct experimental procedures.[482]

9 Benefit Assessment of GoF Research TEST

9.1 Overview of Results

The Benefit Assessment evaluated the potential benefits of GoF experimental approaches involving coronaviruses (CoVs) and influenza viruses to scientific knowledge and public health. Public health benefits included benefits to biosurveillance, to the development of medical countermeasures (MCMs), and to decision-making in public health policy. In each case, the ability of GoF approaches to address gaps in scientific knowledge or shortcomings in public health was compared to the ability of alternative approaches to address those same gaps, which enabled identification of the unique benefits of GoF research. Two types of alt-GoF approaches were considered: alternative experimental approaches that can provide the same or similar information and alternative scientific or technical innovations that can address the same public health gaps through completely different mechanisms. Of note, unlike the risk assessment, the benefit assessment was limited to the evaluation of GoF approaches that have been described in the scientific literature.

Within the field of CoV research, GoF approaches in the following phenotypic categories were identified: enhanced pathogen production, altered host range, enhanced virulence, and evasion of therapeutics in development. Within the field of influenza research, GoF approaches in the following phenotypic categories were identified: enhanced virus production, mammalian adaptation and enhanced transmissibility, enhanced virulence, evasion of vaccines or therapeutics, and evasion of existing natural or induced adaptive immunity. The following figure summarizes the results of the benefit assessment.

GoF Phenotype	Coronaviruses	Seasonal Influenza Viruses	Animal Influenza Viruses	Pathogenic Reassortant Influenza Viruses*
Adaptation to mammals				
Enhanced transmissibility	N/A			
Enhanced pathogenicity				
Evasion of vaccines in development	N/A			
Evasion of existing natural or induced adaptive immunity	N/A		N/A	N/A
Evasion of therapeutics				
Enhanced virus production				
Reassortment (multiple GoF phenotypes possible)	N/A			

**Pathogenic reassortants influenza viruses include reassortants comprised of gene segments from seasonal and pandemic or seasonal and animal influenza viruses.*

Figure 9.1 Summary of the benefits of GoF research by phenotype. White indicates that the phenotypic change cannot be achieved or is not relevant (given the current state of model systems, the current state of MCMs, or the biological characteristics of the virus). Dark grey indicates that the current phenotypic change may be achievable but has not been undertaken in the scientific literature. Light grey indicates that the approach provides unique benefits to scientific knowledge and/or public health. Medium grey indicates that the benefits of GoF approaches and alternative approaches are overlapping; that is, that alt-GoF approaches can address the same scientific knowledge or public health gaps that GoF approaches can address. Note that medium grey does not indicate that GoF and alt-GoF approaches are equally capable of addressing those

gaps, simply that a more nuanced evaluation is needed to understand the relative value of GoF and alt-GoF approaches.

The brief section that follows provides an overview of the GoF benefits identified in each phenotypic category.

9.1.1 Coronaviruses

GoF approaches that alter host range and enhance virulence uniquely enable the development of animal model systems that recapitulate human disease pathogenesis, which are critical for the study of CoV pathogenesis and for establishing the safety and efficacy of candidate vaccines and therapeutics. This manipulation to a new host typically attenuates virulence in the original host (in the case of SARS and MERS-CoV, humans). GoF approaches that enhance virulence are also uniquely capable of demonstrating that live attenuated vaccines (LAVs) do not recover virulence upon growth *in vivo*, an important aspect of safety testing of candidate LAVs. Of note, this particular approach simply increases the human health risk of the attenuated strain to approach that of wild type strains. GoF approaches that enhance virulence represent the most efficient and effective strategy for discovering novel virulence factors, which may be good targets for new therapeutics. However, several alternative strategies for the development of new therapeutics are being actively pursued and have also shown promise. GoF approaches that lead to evasion of therapeutics in development are critical for the development and regulatory approval of new therapeutics. Because these therapeutics are not yet widely available, no increase in human health risk is posed by resistant strains. GoF approaches that alter host range and enhance virulence provide unique benefits to study cross-species adaptation and pathogenicity, but alternative approaches may also be used.

9.1.2 Influenza Viruses

Across all GoF phenotypes, GoF approaches provide unique benefits to the study of the mechanistic basis of the phenotype under study as well as the evolutionary mechanisms driving acquisition of that trait, though alternative approaches may also be used. Alternative approaches have stringent limitations for the study of mechanisms underlying mammalian transmissibility of animal influenza viruses, as animal flu viruses that efficiently transmit in humans do not exist in nature.

GoF approaches that enhance virus production are uniquely critical for their current ability to produce sufficient and timely influenza vaccines for seasonal flu epidemics and flu pandemics; they represent the only strategy for improving existing vaccine production capabilities in the near-term. Of note, these particular approaches attenuate an otherwise pathogenic strain while enhancing its growth properties.

GoF approaches that enhance the infectivity, transmissibility, and virulence of animal flu viruses inform pandemic risk assessments of circulating influenza viruses, which guide downstream decision-making about investments in pre-pandemic vaccine development and other pandemic preparedness initiatives. Specifically, GoF approaches are uniquely critical for strengthening the predictive value of molecular markers for mammalian adaptation, transmissibility, and virulence, which can be used to infer phenotype from sequence for the risk assessment. In general, molecular marker data moderately contribute to the overall risk associated with a particular virus. However, molecular marker data play an important role in rapid risk assessments when novel flu viruses first emerge in human populations due to the early availability of viral sequence data. These risk assessments facilitate more rapid initiation of response activities such as pre-pandemic vaccine development. Of note, realization of these benefits is subject to significant advancements in the state of knowledge about mechanisms underlying mammalian adaptation,

transmissibility, and virulence, as well as expansion of sequencing capabilities across public health laboratories involved in influenza surveillance.

GoF approaches that enhance the infectivity and virulence of influenza viruses are also used to develop animal models that support the study of disease pathogenesis and medical countermeasure (MCM) development. GoF approaches that lead to evasion of therapeutics in development are critical for the development and regulatory approval of new therapeutics. Of note, the acquisition of resistance to novel classes of therapeutics is not expected to confer cross-resistance to existing antivirals (i.e., adamantanes or neuraminidase inhibitors). Thus, when these experiments involve drug candidates within new classes of therapeutics, which are not yet widely available, no increase in human health risk is posed by resistant strains. However, similar approaches using licensed therapeutics inform therapeutic recommendations for seasonal influenza infections and pandemic preparedness initiatives for high-risk animal influenza viruses, but phenotypic approaches for antiviral sensitivity testing are also used for these purposes. GoF approaches that lead to evasion of vaccines are uniquely capable of determining whether viruses can acquire mutations to escape neutralization of candidate broad-spectrum or universal influenza vaccines, a critical aspect of testing the potential field efficacy of vaccines in development. Most of these experiments involve next-generation influenza vaccine candidates targeting epitopes other than the globular head domain of the hemagglutinin (HA) protein, the target of current influenza vaccines. Given that the globular head domain of HA is the immunodominant protein of influenza viruses and that these next-generation vaccines are not yet widely available, strains that can overcome the protection afforded by these vaccines are expected to pose a minimal increase in human health risk relative to wild type strains. GoF approaches that lead to evasion of existing natural or induced immunity have potential to improve the efficacy of seasonal influenza vaccines, but this benefit is subject to advancements in the state of knowledge about the mechanistic basis of antigenic drift as well as expansion of sequencing capabilities across public health laboratories involved in global influenza surveillance. Finally, GoF studies involving reassortment, which may lead to one or more phenotypic changes, are uniquely capable of providing information that can be used to prioritize community-level interventions aiming to prevent opportunities for co-infections that could lead to the generation of reassortant viruses with phenotypic properties of concern.

9.1.3 Summary

Chapter 9 provides a relatively brief description of all of the benefits of GoF research that were identified in this study. Chapter 15 provides a fully referenced and in-depth discussion of these findings and includes a summary table for each GoF benefit, which describes the relative strengths and limitations of GoF and alt-GoF approaches that can achieve that benefit. As the relative ability of a given GoF (or alt-GoF) approach to address a particular scientific knowledge or public health gap often hinges on nuanced differences between the benefits and limitations of different approaches, readers who seek an in-depth understanding of the benefits of GoF research are directed to chapter 15.

The following table summarizes the set of benefits identified for each GoF phenotype and directs readers to the relevant sections and summary tables that accompany each benefit.

Table 9.1. List of Potential Benefits of GoF Research Involving Coronaviruses

Benefit Category	Potential Benefit	Unique Benefit?*	Sections	Crosswalk Table(s)	Time Horizon for Benefit Realization	Time Horizon - Notes
Enhanced virus production						
Scientific Knowledge	Develop *in vitro* model systems for studying bat CoVs	Partial	9.3.5.1.1; 15.1.4.1	15.3	Immediate	N/A
Altered host range (mammalian adaptation)						
Scientific Knowledge	Gain insight into mechanistic basis of cross-species adaptation	Partial	9.3.5.1.1; 15.1.3.1	15.1	Immediate	N/A
Scientific Knowledge	Develop *in vitro* model systems for studying bat CoVs	Partial	9.3.5.1.1; 15.1.4.1	15.3	Immediate	N/A
Scientific Knowledge	Develop animal models for studying CoV pathogenesis	Partial	9.3.5.1.3; 15.1.4.2	15.4	Immediate	N/A
Vaccines and therapeutics	Develop animal models for testing candidate MCMs	Partial	9.3.5.4.1; 15.1.4.2	15.4	Long term	Development and licensing of new MCMs is a long process
Vaccines and therapeutics	Develop model system for testing broad-spectrum efficacy of MCMs	Partial	9.3.5.4.2; 15.1.5.3	15.8	Long term	Development and licensing of new MCMs is a long process
Enhanced virulence						
Scientific Knowledge	Gain insight into mechanistic basis of CoV virulence	Partial	9.3.5.1.2; 15.1.3.2	15.2	Immediate	N/A
Scientific Knowledge	Develop animal models for studying CoV pathogenesis	Partial	9.3.5.1.3; 15.1.4.2	15.4	Immediate	N/A
Vaccines and therapeutics	Develop animal models for testing candidate MCMs	Partial	9.3.5.4.1; 15.1.4.2	15.4	Long term	Development and licensing of new MCMs is a long process

Table 9.1. List of Potential Benefits of GoF Research Involving Coronaviruses

Benefit Category	Potential Benefit	Unique Benefit?*	Sections	Crosswalk Table(s)	Time Horizon for Benefit Realization	Time Horizon - Notes
Therapeutics	Identify new therapeutic targets	Partial	9.3.5.3.1; 15.1.5.2	15.6	Long term	Development and licensing of new therapeutics is a long process
Vaccines	Support development of live attenuated vaccines	Yes	9.3.5.2; 15.1.5.1.1	15.5	Long term	Development and licensing of new vaccines is a long process
Evasion of therapeutics in development						
Therapeutics	Gain insight into therapeutic's mechanism of action	Partial	9.3.5.3.2; 15.1.5.2.2.	15.7	Long term	Development and licensing of new therapeutics is a long process
Therapeutics	Facilitate regulatory approval of new therapeutics	Yes	9.3.5.3.2; 15.1.5.2.3	N/A	Long term	Development and licensing of new therapeutics is a long process
Therapeutics	Inform development of therapeutic strategies that minimize development of resistance	Yes	9.3.5.3.3; 15.1.5.2.4	N/A	Long term	Development and licensing of new therapeutics is a long process

**The "Unique Benefit" column indicates whether the benefit indicated in the previous column is unique or whether alt-GoF approaches can achieve the same general benefit. "No" indicates that alt-GoF approaches can provide nearly identical benefits, with respect to the quality, scope, and timeliness of the benefit; "Yes" indicates that alt-GoF approaches cannot provide the same benefit; and "Partial" indicates that alt-GoF approaches can provide similar benefits but may be limited in some way when compared to the GoF approach. Of note, a "Partial" entry does not indicate that the potential benefits of GoF and alt-GoF approaches are the same but rather that a more nuanced evaluation is needed to understand the relative benefits of GoF and alt-GoF approaches.*

Seasonal, animal	Surveillance	Inform assessment of the risks posed by reassortant viruses detected through surveillance	Partial	9.11.5.2; 15.8.4	15.38	Long term	Surveillance for reassortant viruses is poor and must be improved for realization of this benefit.
Seasonal, animal	Policy	Inform pandemic risk assessment of animal flu viruses and downstream decision-making about investments in pandemic preparedness activities	Partial	9.11.5.3.2; 15.8.5.2	15.19	Long term	Surveillance for reassortant viruses is poor and must be improved for realization of this benefit.
Seasonal, animal	Policy	Inform prioritization of interventions that aim to prevent the emergence of novel reassortant viruses in human populations	Yes	9.11.5.3.1; 15.8.5.1	N/A	Near term	N/A

Table 9.2. List of Potential Benefits of GoF Research Involving Influenza Viruses

Agent (Influenza Virus Strains)*	Benefit Category	Potential Benefit	Unique Benefit?**	Sections	Crosswalk Table(s)	Time Horizon for Benefit Realization	Time Horizon - Notes

** Animal strains include avian and swine strains that have and have not infected humans. Pandemic strains include the 1918 H1N1, 1957 H2N2, and 1968 H3N2 viruses. Seasonal strains include all seasonal isolates and 2009 H1N1 pandemic isolates (now circulating seasonally). The "Agent" column includes all strain types that have been subjected to a Gain of Function using the listed approach. Of note, pandemic strains are not listed in the "Enhanced Virulence" section because while these studies include the generation of reassortant strains including genes or gene segments from pandemic strains, the resulting reassortant strains are expected to be less virulent than the wild type pandemic strains.*

***The "Unique Benefit" column indicates whether the benefit indicated in the previous column is unique or whether alt-GoF approaches can achieve the same general benefit. "No" indicates that alt-GoF approaches can provide nearly identical benefits, with respect to the quality, scope, and timeliness of the benefit; "Yes" indicates that alt-GoF approaches cannot provide the same benefit; and "Partial" indicates that alt-GoF approaches can provide similar benefits but may be limited in some way when compared to the GoF approach. Of note, a "Partial" entry does not indicate that the potential benefits of GoF and alt-GoF approaches are the same but rather that a more nuanced evaluation is needed to understand the relative benefits of GoF and alt-GoF approaches.*

**** Studies that lead to the generation of variant strains of the 1918 H1N1 pandemic virus with altered antigenicity were not identified. However, several antigenic escape studies involving a classical swine H1N1 isolate from 1930 (A/Swine/Iowa/15/30), the HA sequence of which more closely resembles the 1918 HA sequence than the sequence of any other existing isolate, were identified. Of note, this 1930 strain is not known to infect humans, although more recent classical swine viruses can infect people.*

9.2 Methodology

9.2.1 Purpose of This Task

The purpose of the qualitative benefit assessment (BA) is to provide information regarding the potential benefits of GoF research to scientific knowledge, public health, and medicine, including benefits to biosurveillance, decision-making in public health policy, and the development of vaccines, therapeutics, and diagnostics. (Throughout the report, the term "public health" is used to encompass all applied benefits to public health and medicine.) Economic benefits were not explicitly evaluated but are noted where relevant. Similarly to the risk assessment, the benefit assessment will be comparative: that is, the benefits of GoF studies are evaluated relative to the benefits of alternative experimental approaches that can provide similar information or other scientific and technical innovations that can provide similar benefits. In addition, the BA will seek to provide information regarding barriers to the realization of the benefits and the global distribution of the benefits, two key considerations when weighing the potential benefits against research risks that may be global and immediate.

9.2.2 Conceptual Approach to the Identification of Potential Benefits of GoF Research

The approach to the benefit assessment is founded on the concept that the benefits of scientific research derive from applications of new scientific information or products to unanswered scientific questions or unmet needs in public health and medicine (collectively referred to as "gaps"). To that end, a multi-step process was used to identify the benefits of GoF research relative to alternative approaches, as illustrated in Figure 9.2. First, a foundation for the analysis of benefits was established by independently (a) characterizing the expected scientific information and products derived from GoF studies of potential concern involving Pathogens with Pandemic Potential (PPPs), and (b) identifying gaps in scientific knowledge about PPPs as well as gaps in public health and medical capabilities related to the prevention and control of PPP outbreaks. Second, the scientific information/products derived from GoF research were mapped ("crosswalked") to the gaps in scientific knowledge and public health. That is, for each scientific outcome of GoF research, the gaps in scientific knowledge and public health that the information/product could address were identified; subsequently, the mechanism by which the information/production could overcome shortcomings in that gap area was determined. This crosswalk analysis was guided by the proposed benefits of GoF research, as suggested by infectious disease researchers and "translators" involved in the application of research to public health challenges. The outputs of the crosswalk analysis–GoF research applications and their downstream effects on the health of human populations–represent the potential benefits of GoF research. Third, alternate experimental approaches and/or other scientific or technical innovations that could lead to the same or similar benefits were identified. Fourth, the barriers to the realization of GoF and alt-GoF benefits were assessed, including factors that impede the translation of the research as well as "downstream" factors that limit its ultimate impact on human morbidity and mortality. Comparative analysis of the benefits afforded by GoF research versus alternative approaches, in light of the barriers to the realization of each approach, yielded insight into the unique benefits of GoF research. Fifth (not shown in Figure 9.2), the globalization potential of GoF benefits found to be uniquely beneficial were analyzed. Lastly, the impact of GoF benefits to the production of influenza vaccines on the public health burden of seasonal flu epidemics and flu pandemics was quantitatively analyzed.

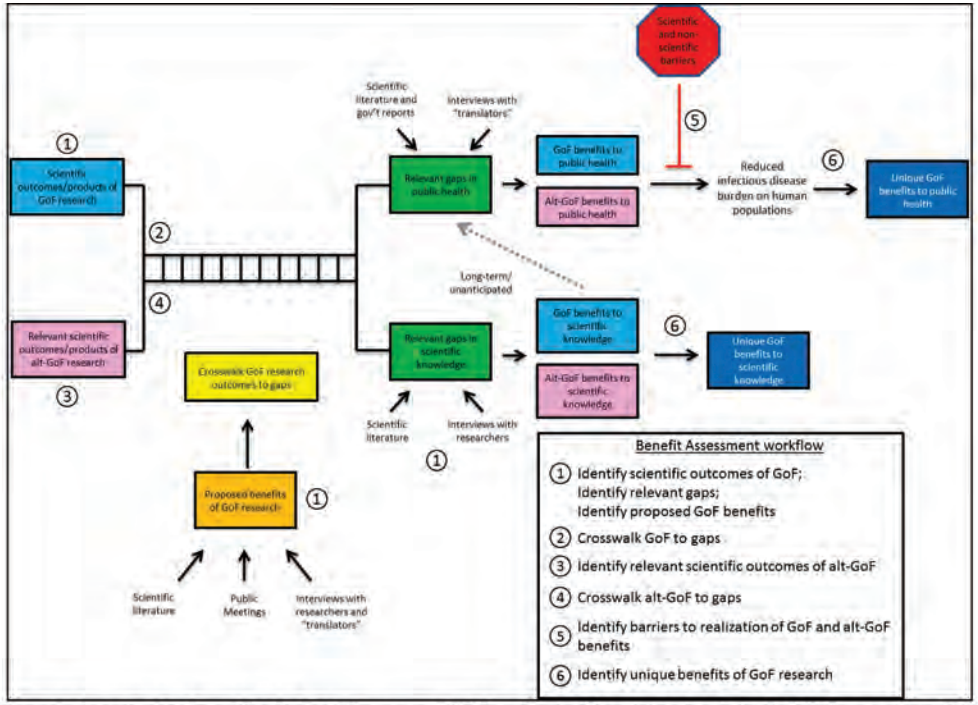

Figure 9.2. Conceptual approach and workflow for benefit assessment. "Relevant" scientific outcomes/products of alt-GoF research are those outcomes that can address similar gaps as GoF research. "Relevant" gaps in scientific knowledge and public health are those gaps that can be addressed by GoF research. Strategies for identifying the relevant outcomes and gaps will be described in detail below. Because the applications of new scientific knowledge to public health are long-term and unanticipated (e.g., whether a newly discovered virulence factor is a good therapeutic target), the barriers to realization of these long-term benefits will not be evaluated.

9.2.3 Characterizing the Expected Scientific Information and Products Derived From GoF Studies

The scientific body of work that falls within the definition of GoF research on PPPs was analyzed, as informed by the NSABB's Framework for Conducting Risk and Benefit Assessments of Gain of Function Research and the USG funding moratorium on certain types of GoF research. Specifically, this analysis included scientific research involving seasonal influenza viruses, pandemic influenza viruses (e.g., 1918 pandemic influenza virus), swine influenza viruses, and avian influenza viruses, as well as research involving SARS coronavirus, MERS coronavirus, and SARS/MERS-like bat coronaviruses. Within each field of research, all experimental approaches that are reasonably anticipated to confer one or more of the following phenotypic changes were evaluated:

- Enhanced pathogen production as a result of changes in the viral replication cycle or growth,
- Enhanced morbidity and mortality in appropriate animal models,
- Enhanced transmission in mammals, including altered host or tissue range and more efficient transmission by contact or airborne routes,
- Evasion of existing natural or induced immunity, and
- Evasion of vaccines, therapeutics or diagnostics.

Subsequently, within each GoF phenotype and for influenza viruses and coronaviruses separately, a set of general experiments that capture the range of GoF studies conducted in the published literature was defined and termed the "landscape" of GoF research. Each general experiment is described by:

- Experimental goal(s) (e.g., gain insight into mechanisms of airborne transmissibility of influenza viruses),
- Experimental approach (e.g., serial passaging of influenza virus in ferrets with selection for airborne transmission),
- Virus strains that are used (e.g., animal-origin influenza strains), and
- Expected research output(s), including new scientific information and/or products (e.g., gain insight into molecular mechanisms of airborne transmissibility of influenza viruses between mammals and identify genetic determinants of airborne transmissibility in influenza viruses).

The list of expected scientific outcomes/products of GoF research of potential concern served as the inputs of our crosswalk analysis. Specifically, scientific outcomes/products were mapped to gaps in scientific knowledge, public health, and medicine in order to assess their potential benefits to science and society.

9.2.4 Identifying Proposed Benefits of GoF Research to Scientific Knowledge, Public Health, and Medicine

Specific proposed benefits of GoF research to scientific knowledge and public health ("pro" arguments) were identified, as described by three categories of stakeholders:

- Scientific researchers who study influenza, SARS, and MERS, including those who conduct GoF studies of potential concern and those who employ alternative approaches,
- Other scientists from the public health, agricultural, and wildlife research communities, and
- "Translators" involved in applying GoF research to public health and medicine.

Critiques of proposed benefits ("con" arguments) were also identified. Proposed benefits (and associated benefit critiques) were researched in all benefit areas defined in the NSABB Framework for Conducting Risk and Benefit Assessments of Gain of Function Research (i.e., scientific knowledge, biosurveillance, medical countermeasures, decision-making in public health policy, and economic benefits). Additional benefits proposed by stakeholders that fell outside of the Framework areas were also explored.

The identification of proposed benefits and benefit critiques was carried out in several stages. First, a complete list of benefits and benefit critiques publicized by GoF stakeholders was compiled, drawing on several sources of information:

- Public meetings about GoF research, such as the October 2014 National Academies Workshop on GoF Research and past National Academies and NSABB meetings,
- Perspectives published in scientific journals, and
- Research articles and reviews published in the scientific literature.

Second, each proposed benefit and benefit critique was researched in greater detail through interviews with GoF stakeholders involved in conducting scientific research, including researchers studying influenza viruses, coronaviruses, and other infectious diseases, and stakeholders involved in translating research insights into public health practice and policy. Of note, the list of GoF stakeholders interviewed included numerous "vocal participants" in the GoF debate who had written opinion pieces about GoF research. (See "Using Interviews to Inform the BA," below, for a more detailed description of the types of stakeholders interviewed for the BA and Appendix 15.10 for a list of interviewed stakeholders.) Each interviewee was subjected to a point-counterpoint style debate about his or her proposed benefits and benefit critiques, enabling Gryphon to elucidate nuanced aspects of each argument.

Finally, this list of proposed benefits and benefit critiques was expanded upon through further examination of the scientific literature, including the basic science literature involving PPPs and the literature on infectious disease surveillance, MCM development, and public health policy. In particular, further analysis of the basic science literature was critical to identifying specific potential benefits of GoF studies to scientific knowledge.

Taken together, the information gleaned from interviews and other sources enabled the development of a list of proposed benefits of GoF research to scientific knowledge and public health and associated benefit critiques, which informed two aspects of the subsequent analyses. First, a set of public health areas that encompass all proposed GoF benefits was defined (e.g., pandemic risk assessment using surveillance data, development of influenza vaccines, etc.), which were subjected to a gap analysis as described below. Second, the list of proposed benefits of GoF research guided the crosswalk of the outputs of GoF research to gaps in scientific knowledge and public health. As described below, this crosswalk involved validation of each proposed benefit through examination and analysis of the scientific literature (for benefits to scientific knowledge) or through interviews with stakeholders in public health and MCM development

who are directly involved in applying the data or agents generated through GoF research to public health practice and policy and MCM development/production.

9.2.5 Identifying Current Practices in Medical Countermeasure Development and Production That Rely on GoF Approaches

Following the identification of the proposed benefits of GoF research, whether and how GoF approaches contribute to current practices in the development and production of influenza virus and coronavirus MCMs were explicitly determined. First, FDA regulations related to the approval of MCMs were analyzed to determine whether GoF studies facilitate or are essential for any aspects of the process, including analysis of whether resistance studies are required for the approval of new therapeutics or vaccines, the role of the Animal Rule in the demonstration of MCM safety and efficacy, and other relevant regulations. Second, the role of GoF approaches in current processes for egg- and cell-based vaccine production was reviewed through analysis of the academic literature and through interviews with industry and government personnel with expertise in influenza vaccine production. The continued application of GoF research to these areas represents one type of potential benefit of GoF research.

9.2.6 Identifying Gaps in Scientific Knowledge About PPPs and Gaps in Public Health and Medical Capabilities Related to the Prevention and Control of PPP Outbreaks

This task involved the identification of gaps in scientific knowledge about PPPs and gaps in public health and medical capabilities related to the prevention and control of PPP outbreaks that could potentially be addressed by insights gleaned from GoF research. This analysis was undertaken for several reasons. First, identification of alternative approaches that aim to address the same or similar gaps as GoF studies requires a complete and nuanced understanding of the gaps and their role in the overall public health process, as alternative approaches may benefit the same ultimate public health gap (e.g., delayed availability of vaccines during an influenza pandemic) by addressing different shortcomings in the process (e.g., increasing the rate of vaccine production versus developing pre-pandemic vaccines that can be rapidly deployed during a pandemic). Second, this gap analysis enabled identification of scientific and non-scientific barriers to the realization of the benefits.

Many gaps in public health and medicine cannot be addressed by biomedical research. Broadly speaking, the scope of this analysis was bounded by the list of GoF benefit areas defined in the task above, including biosurveillance, development and production of vaccines and therapeutics, and decision-making for public health preparedness. Within each benefit area, the list of proposed benefits was further utilized to focus on identifying and researching gaps that could be targeted by GoF research. Importantly, gaps were evaluated independently of their relationship to GoF research. To understand critical gaps in scientific knowledge about PPPs, the state of the science regarding how influenza viruses, SARS-CoV, and MERS-CoV are transmitted between hosts, cause disease, overcome protective immunity, and evolve new phenotypic characteristics was reviewed. Interviews with researchers and "translators," as well as an analysis of the scientific literature, provided information about gaps in public health and medicine. Notably, this research attempted to identify not only the gaps that could be addressed by GoF studies, but also who may use the outputs of GoF studies to address the gaps, so that these stakeholders could be interviewed to validate the assessment of the benefits of GoF research (described below).

9.2.7 Crosswalking GoF Research Outcomes to the Gaps in Scientific Knowledge, Public Health, and Medicine

The next phase of the analysis determined how the research outputs of GoF studies can address gaps in scientific knowledge, public health, and medicine. This "crosswalk" was guided by the proposed benefits of GoF research. Each proposed benefit was validated through analysis of the scientific literature (for benefits to scientific knowledge) or through interviews with "translators" who are directly involved in applying the data or agents generated through GoF studies to public health and MCM development/production. Critically, this analysis included an assessment of the relevance and validity of all benefit critiques previously identified, including concerns about whether and when the benefits will be realized. Throughout the benefit validation process, GoF stakeholders were re-engaged as needed to solicit additional information necessary to validate a given benefit or benefit critique or to clarify previous remarks.

Benefits to scientific knowledge have intrinsic value while benefits to public health apply to "upstream" aspects of the public health process (e.g., biosurveillance), the ultimate goals of which are reducing human morbidity and mortality caused by influenza viruses and coronaviruses. To understand all of the steps needed to realize the public health benefits from discovery to immediate application to ultimate impact on public health, the analyses of public health systems were leveraged. For example, genetic markers that confer high growth to vaccine viruses, identified through GoF studies, are incorporated into vaccine viruses used for manufacturing in order to shorten production timelines by increasing the rate of viral antigen production. In turn, these improvements to the vaccine production process lead to faster vaccine availability during a pandemic, which reduces morbidity and saves lives. Finally, for benefits related to the production of influenza vaccines, the effects of improving the availability vaccines on human morbidity and mortality during outbreaks were further evaluated using quantitative methods, as described in the "Quantitative Analysis of GoF Benefits" section below. Collectively, the outputs of the crosswalk analysis – GoF research applications and their downstream impacts on the health of human populations – represent the potential benefits of GoF research. Notably, realization of some public health benefits may depend on other scientific and non-scientific factors, the implications of which are explored in our assessment of barriers to the benefits, described below.

9.2.8 Assessing the Barriers to the Realization of GoF and Alt-GoF Studies

One of the most challenging aspects of weighing the risks and benefits of GoF research is that there is a temporal mismatch between the risks and the benefits of the research–the risks are assumed at the time the research is conducted, while the benefits to public health and medicine *may* accrue in the future. To enable the comparison of risks and benefits, the benefit assessment is structured to provide data about the probability and likelihood that the potential benefits of GoF research will be realized.

To accomplish this goal, benefits to scientific knowledge and benefits to public health/medicine were considered separately. Scientific insights have immediate intrinsic value and may also inform the development of novel vaccines or therapeutics, surveillance strategies, and other advancements in public health/medicine in the future. Because the nature and timing of such applications are difficult to predict with certainty, this report acknowledges but does not attempt to elucidate or evaluate the unforeseen applications of basic science research to public health or medicine for this analysis.

In contrast, the potential benefits of GoF research to public health/medicine involve clear applications of scientific information gleaned through GoF studies to unmet needs in public health. However, unlike the risks, which pose possible direct threats to humans, animals, and the environment, the benefits involve "upstream" aspects of the public health process, and evaluating how and when the benefits will improve

the health of human populations is complex. That is, translation of the research may depend on other scientific, technical, and regulatory factors (e.g., the need to gain FDA approval in order to market a new therapeutic). Additionally, gaps or inefficiencies in downstream aspects of the public health process (e.g., limited funding for investment in the development of pre-pandemic vaccines) may limit the ultimate impact of the research application on human health. Collectively, these factors function as "barriers" that reduce the likelihood and delay the timing of the realization of the benefits, although significant uncertainties in when and whether barriers can be overcome preclude a meaningful quantitative estimate of either parameter.

For those validated benefits to public health, the barriers that may impede or delay realization of the benefits were identified in two stages. First, the state of the science and the limitations of the experimental approach that could influence the nature and scope of the benefit were considered. For example, a set of mutations that confer efficient transmissibility to one strain of zoonotic influenza, identified through a GoF experiment, may not lead to the same phenotypic changes in a different genetic context, and the current ability to predict the phenotypic consequences of mutations in new strains is sub-par. Together, these sources of scientific uncertainty represent scientific barriers that compromise the utility of this information in aiding analysis of biosurveillance data. Subsequently, scientific advancements needed to overcome these scientific uncertainties were defined.

Second, the gap analysis of public health capabilities was leveraged to elucidate the non-scientific barriers to the realization of each potential benefit and to determine the type of resources or advancements that are required to overcome or circumvent each barrier. These advancements include investments in public health infrastructure (e.g., expanding global influenza surveillance networks), investments in MCM development infrastructure (e.g., increasing the number of cell-based and other non-traditional influenza vaccine production facilities), regulatory approval of new MCMs or MCM production processes, and changes in public health policies or regulations. This analysis was informed by the concerns related to benefit realization that were identified in the literature and through interviews with stakeholders. For all aspects of this task, scientists, public health practitioners, MCM developers, public health policy-makers, and other GoF stakeholders previously interviewed were re-engaged as needed to clarify opinions regarding GoF benefits and benefit critiques, challenges in biosurveillance, MCM development, public health policy-making, and other topics.

9.2.9 Assessing if Alternate Experimental and Other Scientific Innovations Could Lead to the Same Benefits

GoF studies comprise a subset of all research activities involving PPPs, and some alternative approaches may pose less risk than GoF studies but yield the same or similar benefits. Two types of "alt-GoF" approaches were considered. First, alternative experimental approaches that can address the same scientific questions as GoF approaches were identified, for example Loss of Function versus Gain of Function approaches for identifying determinants of pathogenicity. The second type of alt-GoF approach considered is other scientific and technical approaches that can address the same public health gaps that GoF can address, but using a completely different strategy. For example, GoF studies that increase the yields of influenza vaccine viruses in eggs or cell culture may benefit influenza vaccine production by shortening the time needed to produce the same number of vaccine doses. However, a completely different strategy, such as the production of recombinant influenza vaccines using insect cells, may also address issues related to the timeliness and amount of vaccine available even though this alternate approach shares no experimental features with the GoF approach. After considering these alt-GoF approaches, the benefit assessment can identify those types of GoF studies that may provide unique benefits to scientific knowledge and public health, which will complement the analysis of the net risks associated with the conduct of GoF research relative to alternative approaches.

Alternative approaches that may yield similar information or public health impacts as GoF research were identified by drawing on the alternative approaches suggested by infectious disease researchers and translators during public meetings about GoF research (such as NSABB meetings and NAS symposia), in perspectives published in scientific journals, and during interviews, as well as the scientific literature on PPPs. Importantly, alt-GoF research spans a wide range of topics, and those alt-GoF studies that yield information outside the scope of GoF research are not relevant for the analysis. For this reason, to focus the analysis on those approaches that may inform the same or similar gaps as GoF research, alt-GoF approaches were identified by starting with the set of scientific knowledge gaps that are targeted by GoF studies and referencing the scientific literature to identify alt-GoF approaches that target those same gaps. The analysis of alternative approaches that target similar public health gaps critically leveraged the analysis of public health systems, in particular the understanding of how the steps from discovery to application of GoF research participate in an overall system.

Subsequently, the potential benefits of alt-GoF approaches were identified through the same process as for GoF studies: a crosswalk of the research outputs of alt-GoF studies or the products of alternative scientific/technical innovations to gaps in scientific knowledge and public health that can be addressed by GoF research. Similarly, the barriers to the realization of alt-GoF benefits were assessed through identification of co-factors needed for the translation and downstream public health impacts of alt-GoF approaches.

Ultimately, the goal of the benefit assessment is to identify the benefits of GoF research of concern relative to alternative experimental approaches that may pose less risk. A list of benefits was compiled, as well as the scientific and non-scientific co-factors required for realization of each benefit, for each GoF research approach of potential concern. To provide a comparison, a similar list was compiled for each alt-GoF approach evaluated. Evaluation of the unique benefits involved comparison of GoF and alt-GoF benefits, in light of barriers to realization of each set of benefits. To identify the unique benefits of GoF research to scientific knowledge, the benefits of GoF research and those of alternative experimental approaches were compared. Identification of the unique benefits of GoF research to public health involved additional comparison of the benefits of GoF research to those of alternative scientific and technical innovations that address the same public health gap through different mechanisms. Beyond an explicit consideration of barriers, a variety of factors were considered when comparing the benefits of GoF research to alt-GoF research, including the ability of an approach to:

- Provide causative versus correlative (associative) data,
- Provide direct evidence of a phenomenon versus indirect evidence (e.g., showing that pathology changes by manipulating the virus vs manipulating the host of a virus),
- Provide the ability to predict potential natural phenomena in the future versus describe the current state of nature,
- Provide evidence in the near term versus the far term, and
- Provide needed evidence with the least effort and resources, including financial resources and laboratory animals (efficiency).

9.2.10 Evaluating the Globalization Potential of GoF Benefits

Whether risks and benefits are equally distributed across populations is also an important consideration in any risk-benefit comparison. For GoF research involving PPPs, the risks– that biosafety or biosecurity incidents associated with the conduct of GoF research involving PPPs may spark a pandemic–are global. In contrast, whether GoF benefits are globally distributed is likely to vary by the type of benefit considered. The extent to which these benefits can be globalized influences whether risks and benefits are equally distributed for a particular type of GoF study. To inform NSABB's deliberations on this issue, the benefit assessment qualitatively assessed the globalization potential of the latter set of GoF benefits, through analysis of historical case studies examining the globalization of similar benefits and through review of relevant USG policies (e.g., policies related to MCM sharing, etc.).

The globalization potential of select GoF benefits, namely those that are relevant worldwide but may be primarily realized in the US and other developed countries, were evaluated. To support this task, USG policies, programs, and international agreements relevant to globalization of GoF benefits were analyzed, including USG policies and international agreements regarding MCM sharing during global outbreaks and other relevant pandemic preparedness support for the World Health Organization (WHO). Also, historical examples of USG involvement in the globalization of GoF benefits were analyzed, considering the context of the historical example and its relevance to a future outbreak of influenza, SARS, or MERS. Taken together, these analyses will enable qualitative assessment of the degree to which the USG promotes globalization of various GoF benefits, as well as the timescale over which those benefits are expected to internationalize.

9.2.11 Quantitative Analysis of GoF Benefits

Although the ability to provide quantitative metrics for benefits would facilitate comparison of the benefits of GoF versus alt-GoF research as well as of the risks and benefits associated with particular types of GoF studies, given the differences in the availability and quality of data related to the realization of the benefits, a quantitative analysis of all benefits cannot be performed. In particular, benefits related to some aspects of MCM development, surveillance, public health policy, and scientific knowledge are associated with multiple sources of uncertainty in how, when, and where the benefits will ultimately improve the health of human populations, which precludes a meaningful quantitative analysis of the magnitude of those effects. However, it is hoped that the rigorous examination of the pathways through which those benefits lead to reductions in the burden of infectious diseases on human populations provide a qualitative sense of the potential scale of each benefit, in light of current barriers to the realization of that benefit.

Benefits related to the production of influenza vaccines are amenable to quantitative analysis, which leverages models developed for the biosafety RA (specifically the nested SEIR models of global outbreaks) to parametrically explore how changes in the control of outbreaks of PPP can mitigate morbidity or mortality. Critically, many factors prevent the absolute assignment of a particular GoF outcome to a quantitative benefit. For this reason, the quantitative approach herein shows how changing a public health or medical capability that can be targeted by GoF research (such as the timeliness of the availability of a vaccine during a pandemic) could affect the consequences of a global outbreak. These data are accompanied by a commentary on the barriers for GoF achieving a desirable change to public health and medical capabilities or preventing a deterioration of public health/medical capabilities so that stakeholders can understand the probability of achieving the quantitative benefits modeled. This quantitative component of the evaluation was accomplished using the HHS-BARDA Interactive Influenza Model (as described in the biosafety RA described above) to parametrically analyze the effect of:

1. The timeliness of availability of a vaccine after an seasonal or pandemic influenza outbreak, and
2. The amount of vaccine available when it becomes available.

For each of these parameters, the value of the parameter was allowed to vary from arbitrarily large numbers to arbitrarily small numbers during simulations of outbreaks of seasonal influenza and pandemic influenza (similar to the pandemic strain of 1918 or 2009). This enabled determination of the value at which each of these parameters begin to affect the consequence of global influenza outbreaks. The change in parameter value needed to significantly change the consequence of a global outbreak was compared with the plausible benefit to the vaccine afforded by GoF and alt-GoF studies, in order to determine if either is likely to have the significant effect on the consequences of an outbreak. Moreover, for GoF studies that are necessary to maintain the status quo for influenza vaccines, this analysis determined how much worse an outbreak would be if those studies were not allowed to continue.

9.2.12 Using Interviews to Inform the Benefit Assessment

As described above, interviews with GoF stakeholders critically informed many aspects of the BA, namely:

- Identification of proposed benefits of GoF research to scientific knowledge and public health, as well as associated benefit critiques,
- Identification of alt-GoF approaches that may yield the same or similar as GoF approaches,
- Validation of the proposed benefits of GoF and alt-GoF research, in particular validation of benefits to public health, and
- Identification of scientific and non-scientific barriers that may impede the realization of GoF and alt-GoF benefits.

To inform each of these steps, Gryphon Scientific reached out to 78 stakeholders from a variety of sectors for interviews, 52 of who agreed to participate in an interview or site visit, resulting in an overall response rate of 66%. The breakdown of response rates by sector is as follows: ~50% for government stakeholders, 80% for industry stakeholders, and ~70% each for non-PPP researchers and PPP researchers. Gryphon staff visited seven influenza and coronavirus research laboratories to collect additional data for the risk assessment through laboratory tours and interviews about biosafety and biosecurity practices (Appendix 15.10). During the site visits, Gryphon also questioned principle investigators and their senior research staff, postdoctoral fellows, and senior graduate students about the benefits of their research to scientific knowledge and public health. These additional discussions with senior researchers and trainees boosted the total number of PPP researchers interviewed for the project.
For interviews focused exclusively on the benefits of GoF research, local interviews were carried out in person, while all other interviews were conducted over the phone. In total, 86 stakeholders were interviewed (Figure 9.3).

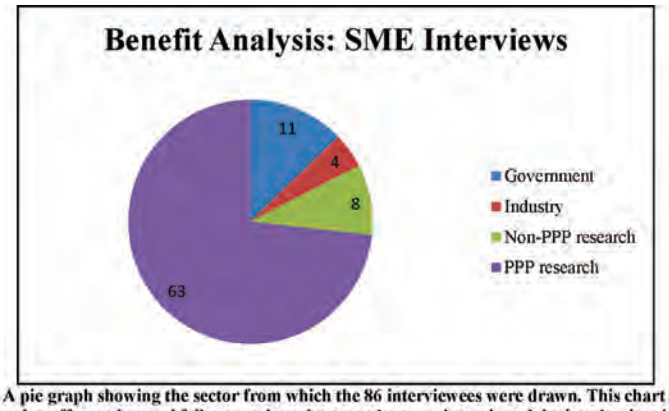

Figure 9.3. A pie graph showing the sector from which the 86 interviewees were drawn. This chart includes senior research staff, postdoctoral fellows, and graduate students we interviewed during the site visits to labs that conduct PPP research. "Translators" include government and industry personnel, as well as some PPP researchers who are involved in translation activities, such as WHO strain selection meetings for the seasonal influenza vaccine. Of note, several government personnel are also actively involved in PPP research.

Given the important role of interview data in the BA, several points concerning the breakdown of interviewees by sector bear further discussion. First, stakeholders from multiple sectors are involved in the conduct and application of GoF research. Specifically, in addition to PPP researchers, several government personnel (e.g., CDC personnel) are actively involved in PPP research. Industry stakeholders may also conduct GoF research, in particular research that enhances the production of influenza viruses in the influenza vaccine production industry. Conversely, regarding "translation" of the benefits to public health/medicine, in addition to government and industry personnel, several PPP researchers participate in translation activities. In particular, PPP researchers are involved in the application of GoF research to biosurveillance, including conducting pandemic risk assessments and participating in WHO strain selection meetings for seasonal influenza vaccines. Second, a diversity of opinions was expressed by stakeholders within all sectors. That is, within each sector, interviewees both espoused and critiqued potential benefits of GoF research. Put another way, multiple "con" arguments were made by those who conduct PPP research, and multiple "pro" arguments were suggested by non-PPP researchers, as well as the converse.

In this context, one salient point is that a greater number of PPP researchers were interviewed than non-PPP researchers. Although the BA would be further strengthened through additional input from stakeholders in every sector, in particular non-PPP researchers and industry stakeholders, the number of the interviews conducted was necessarily limited by the compressed timescale of the project. Gryphon's strategy for selecting the set of interviewees was to ensure that the interviews spanned all unique arguments pertaining to GoF research benefits and benefit critiques. The interviewee list evolved over time, in response to the information and suggestions provided by prior interviewees. Notably, PPP researchers, given their deep and broad expertise in the fields of influenza and coronavirus research, were generally able to speak with much greater depth and nuance about the scientific benefits and caveats associated with both GoF and alt-GoF approaches than non-PPP researchers. As a result, the list of benefits discussed during interviews with non-PPP researchers became "saturated" – that is, additional interviews did not yield novel insights about potential GoF benefits – more quickly than those discussed during interviews with PPP researchers. This phenomenon was one reason that a greater number of interviews with PPP researchers were conducted. A second reason stems from the fact that interviews

with translators informed the validation of proposed benefits. These interviews necessarily targeted those who are directly involved in the applications of GoF research, which included numerous PPP researchers (but not non-PPP researchers).

A second salient point is that the suite of PPP researchers interviewed includes researchers who use GoF approaches, as well as researchers who primarily use alt-GoF approaches but who collaborate with GoF researchers and are co-authors on papers containing GoF experiments. Strikingly, none of the PPP researchers who exclusively publish papers involving alt-GoF approaches were willing to participate in interviews. (One declined and four did not respond to Gryphon's invitation.) Of note, given the broad definition of GoF research provided in the NSABB Framework and used in this assessment, nearly all PPP researchers who engage in "wet lab" research utilize GoF approaches, complicating the identification of a large cohort of PPP researchers who exclusively conduct alt-GoF approaches. Alt-GoF researchers who were contacted primarily employ computational, sequence-based (i.e., phylogenetic analysis), or *in vitro*, virus-free approaches (e.g., biochemical approaches, structural biology approaches, etc.). Importantly, all GoF researchers also use alt-GoF approaches, for a variety of reasons, including risk mitigation, to complement information gleaned from GoF approaches (e.g., GoF and LoF experiments), or when an alt-GoF approach can more effectively answer a particular scientific question than a GoF approach. Collectively, the set of PPP researchers who were interviewed have direct experience conducting nearly every alt-GoF approach identified in this assessment and thus could speak with authority on the scientific knowledge benefits of both GoF and alt-GoF approaches. Because PPP researchers who exclusively employ alt-GoF approaches declined to be interviewed, the question of whether they have substantively different viewpoints on the benefits of alt-GoF approaches could not be determined.

9.3 Coronaviruses: Benefits of GoF research

9.3.1 Summary

This section describes the benefits of GoF research involving coronaviruses (CoVs), which includes (1) approaches that enhance virus production, (2) alter host range, (3) enhance virulence in appropriate animal models, and (4) lead to evasion of therapeutics. Such GoF studies were found to generate scientific knowledge, have direct applications to the development of vaccines and therapeutics, and may also have economic benefits (not considered). Alt-GoF approaches that may generate similar benefits were also identified and analyzed. At present, GoF studies involving CoVs have unique and direct benefits, particularly to the development of vaccines and therapeutics.

9.3.1.1 GoF Approaches That Enhance Virus Production

9.3.1.1.1 Benefits to Scientific Knowledge

- GoF approaches that enhance virus production have potential to enable the development of in vitro model systems for the study of any animal CoV in a variety of cell types, including immortalized and primary cell lines. However, the fact that few animal CoVs identified to date can be grown in existing cell culture systems limits the success of this approach.

9.3.1.2 GoF Approaches That Alter Host Range

9.3.1.2.1 Benefits to Scientific Knowledge

- GoF approaches:

- Are uniquely capable of identifying novel viral genetic traits and factors that contribute to cross-species adaptation, in any CoV strain.
- Are uniquely capable of demonstrating that a particular mutation(s) is necessary and sufficient to alter the host range of a coronavirus.
- Enable the development of in vitro model systems for the study of any animal CoV in a variety of cell types, including immortalized and primary cell lines, and
- Uniquely enable the development of animal models that recapitulate human disease pathogenesis, which can be used to study many facets of disease pathogenesis, including the role of viral and host immune factors in host pathology and the role of tissue tropism in pathology.

- Alternative approaches:
  - Comparative sequence analysis is uniquely capable of identifying genetic traits that are associated with human adaptation, but this approach is limited to the study of CoVs that have already caused human infections and is significantly constrained by the quality and availability of genetic surveillance data for CoVs. In addition, the causality of mutations must be confirmed through a GoF experiment.
  - In vitro approaches, including characterization of the capacity of wild type viruses to infect cells derived from various host species, the use of other viruses pseudotyped with CoV Spike proteins, and binding assays using recombinant proteins, are limited to studying the role of the Spike protein in cross-species adaptation. In addition, results using pseudotyped viruses or recombinant proteins may not be recapitulated in the context of the wild type virus.
  - Use of naturally permissive cell lines to study bat CoVs is limited to the few bat CoVs that can productively infect and replicate within existing cell culture lines.
  - Use of cell lines ectopically expressing permissive receptor proteins to study bat CoVs is limited to cell lines that can be readily transfected, and modifications to cell lines may alter the biology of infection.
  - Naturally susceptible hosts of SARS and MERS cannot be used to study disease pathology because they are asymptomatic or display different symptoms from humans.
  - Transgenic animals that are expressing human receptor proteins do not recapitulate human disease pathogenesis, thus results using transgenic animals may not translate to humans.
  - Though human autopsy data provides direct information about human pathology, limited autopsy data are available and mortalities are not representative of all cases, limiting the generalizability of results.
  - Alternative coronaviruses such as mouse hepatitis virus (MHV) can be used to gain insight into basic aspects of CoV biology but are sufficiently distinct from human CoVs that they are not suitable for the study of pathogenesis.

9.3.1.2.2 Benefits to Vaccine Development

- GoF approaches:

- Uniquely enable the development of animal models that recapitulate human disease pathogenesis, which support testing of the safety and efficacy of candidate vaccines in a robust system that can be used to demonstrate that vaccines reduce disease-associated pathology and can reveal whether vaccines have adverse side effects, and
- Are uniquely capable of providing reliable information about the broad-spectrum potential of CoV vaccines, through the use of chimeric bat-SARS CoVs as vaccine challenge viruses.

- Alt-GoF approaches:
  - Other animal models (naturally susceptible hosts and transgenic animals) do not recapitulate human disease pathogenesis, and thus are weak systems for demonstrating the efficacy of vaccine candidates and cannot reveal adverse side effects.
  - Few wild type bat CoVs can be cultured in existing cell lines, and bat CoVs do not naturally infect mice, thus wild type bat CoVs have limited utility for the development of broad-spectrum vaccines.
  - Vaccine efficacy results using viruses pseudotyped with CoV Spike proteins must be confirmed in wild type (or chimeric CoV strains) due to significant differences in the surface presentation of Spike proteins.

9.3.1.2.3 Benefits to Therapeutic Development

- GoF approaches:
  - Uniquely enable the development of animal models that recapitulate human disease pathogenesis, which support testing of the safety and efficacy of candidate therapeutics in a robust system that can be used to demonstrate that therapeutics reduce disease-associated pathology,
  - Are uniquely capable of providing reliable information about the broad-spectrum potential of CoV therapeutics, through the use of chimeric bat-SARS CoVs as vaccine challenge viruses.

- Alt-GoF approaches:
  - Other animal models (naturally susceptible hosts and transgenic animals) do not recapitulate human disease pathogenesis, and thus are weak systems for demonstrating the efficacy of vaccine candidates and do not satisfy the FDA Animal Efficacy Rule.

9.3.1.3 GoF Approaches That Enhance Fitness or Virulence in Cell Culture or Animal Model Systems

It should be noted that serial passaging of viruses in mice both alters the host range of the virus and enhances its virulence in mice. The value of GoF benefits derived from the use of mouse-adapted viruses, relative to alternative approaches, was summarized in Section 9.3.1.2 (GoF approaches that alter host range) and will not be repeated in this section.

9.3.1.3.1 Benefits to Scientific Knowledge

- GoF approaches:
  - Represent the most efficient and effective strategy for identifying novel genetic traits and viral factors that contribute to virulence, in any CoV strain, and

- Are uniquely capable of demonstrating that a particular mutation(s) is necessary and sufficient to enhance the fitness/virulence of a coronavirus.

- Alt-GoF approaches:
  - Comparative sequence analysis is uniquely capable of identifying genetic traits that are associated with enhanced virulence in humans but is limited to the study of SARS and MERS and is significantly constrained by the quality and availability of genetic surveillance data for CoVs. In addition, any hypotheses must be experimentally confirmed.

  - Loss of Function approaches (i.e., screening gene knockout viruses in vitro) are limited to the discovery of viral factors involved in replication and may uncover factors that indirectly contribute to virulence. Though targeted mutagenesis can be used to confirm that a genetic trait is necessary for virulence, this LoF approach provides limited information about how proteins cooperate to enhance virulence, which is a complex, multi-genic trait.

9.3.1.3.2 Benefits to Vaccine Development

- GoF approaches:
  - Are uniquely capable of determining whether live attenuated vaccine viruses (LAVs) recover virulence upon growth in cells or animals, a critical aspect of safety testing for this type of vaccine, and

  - Represent the most efficient and effective strategy for identifying novel virulence factors, which can be deliberately attenuated to generate LAVs, a promising type of CoV vaccine platform.

- Alt-GoF approaches:
  - Alternative experimental approaches for identifying virulence determinants are less efficient than GoF approaches and are primarily limited to the study of known virulence factors, limiting their utility for informing LAV development.

  - Other types of vaccine platforms that do not rely on GoF approaches have strengths and limitations relative to LAVs, which may rely on GoF for their development.

9.3.1.3.3 Benefits to Therapeutic Development

- GoF approaches:
  - Represent the most efficient and effective strategy for identifying novel virulence factors, which are potential therapeutic targets.

- Alt-GoF approaches:
  - Alternative experimental approaches for identifying virulence determinants are less efficient that GoF approaches and are primarily limited to the study of known virulence factors, limiting their utility for discovering potential new therapeutic targets.

  - High-throughput screening of small molecule compounds for their ability to reduce viral replication in vitro has generated promising therapeutic candidates, but such screens are limited to the discovery of drugs that inhibit viral replication, only one aspect of virulence.

- High-throughput screening of monoclonal antibodies (mAbs) for their ability to bind CoV Spike proteins has generated promising therapeutic candidates, but mAb-based therapeutics have several drawbacks, including the fact that CoV Spike proteins can readily acquire escape mutations.

9.3.1.4 GoF Approaches That Lead to Evasion of Therapeutics in Development

9.3.1.4.1 Benefits to Therapeutic Development

- GoF approaches:
  - Are uniquely capable of determining the genetic threshold for resistance of a candidate therapeutic prior to field deployment of the therapeutic, which is a recommended component of an Investigational New Drug application to the FDA,
  - Are uniquely capable of identifying the viral target of a novel therapeutic with an unknown mechanism of action,
  - Provide insight into the mechanism of activity of a therapeutic through the identification of mutations that are necessary and sufficient to confer resistance to the therapeutic, which is a recommended component of an Investigational New Drug application to the FDA, and
  - Are uniquely capable of determining the therapeutic dose that is least likely to lead to the acquisition of antiviral resistance as well as determining whether combination therapies better prevent the emergence of resistant viruses than individual therapies, which informs the development of therapeutic strategies that will be effective for a longer time in the field.
- Alt-GoF approaches:
  - X-ray crystallography and photoaffinity crosslinking are limited to the study of therapeutics with known viral targets, and inferring mechanistic information based on static data about drug-viral interactions may be difficult.
  - RNAi screens to identify host factors that are required for the antiviral activity of a therapeutic provide indirect information about the mechanisms of therapeutics that target viral proteins.

GoF approaches that benefit the development of vaccines and therapeutics may lead to downstream economic benefits, which were not analyzed in this report. GoF approaches involving coronaviruses do not benefit surveillance, informing policy decisions, or the development of diagnostics.

9.3.2 Overview of the GoF Research Landscape Involving Coronaviruses

This assessment describes the benefits of GoF experiments involving SARS-CoV, MERS-CoV, and SARS/MERS-like bat CoVs. From a review of the coronavirus literature, experimental approaches were identified that are reasonably anticipated to lead to the following phenotypic changes:

- Enhanced pathogen production as a result of changes in the replication cycle or growth,
- Altered host range (typically accompanied by enhanced virulence in the new host),
- Enhanced fitness or virulence in cell culture or laboratory animal model systems respectively, and

- Evasion of therapeutics in development.

As current animal models for studying coronaviruses do not support transmission between animals, this field does not include any approaches that lead to enhanced transmission in appropriate animal models. Additionally, because there is no widespread population immunity to the coronaviruses and there are no licensed coronavirus vaccines, this field does not include any approaches that lead to evasion of existing natural or induced immunity. Finally, no coronavirus research that is reasonably anticipated to lead to evasion of diagnostics or of vaccines in development was identified. (Additionally, there are currently no FDA-approved vaccines or therapeutics for coronaviruses.)
Of note, the four human coronaviruses that cause mild to moderate respiratory illnesses such as the common cold or croup (coronaviruses HKU1, OC43, 229E, and NL63) were not evaluated because these are not considered in the NSABB GoF Framework. Throughout this report, the use of the term "coronaviruses" or "CoVs" refers specifically to SARS-CoV, MERS-CoV, and SARS/MERS-like bat CoVs such as HKU4 and HKU5.

The following chapter summarizes the results of the assessment of the benefits of GoF research involving coronaviruses. A more detailed analysis to further support the findings described in Chapter 9.3 is presented in Appendix IV Section 15.I. As the relative ability of a given GoF (or alt-GoF) approach to address a particular scientific knowledge or public health gap often hinges on nuanced differences between the benefits and limitations of different approaches, readers who seek an in-depth understanding of the benefits of GoF research are directed to chapter 15.

In the following section, a brief overview of the experimental approaches within each GoF phenotypic category is provided and the scientific outcomes and/or products of each approach are described.

9.3.2.1 Experimental Approaches That Lead to Enhanced Pathogen Production

Serial passaging of CoV in cell culture leads to the generation of higher-yield viruses. This approach is used to enhance the growth of viruses with naturally poor growth properties, in order to develop an *in vitro* model system for experimental use.

9.3.2.2 Experimental Approaches That Alter host Tropism in Mammals

Several experimental approaches alter the host range of CoVs. One approach involves "Spike swapping" – that is, targeted genetic modification to replace all or part of the coronavirus Spike protein, a viral surface protein that mediates virus entry into cells and is a critical determinant of host restriction, with the Spike protein from another CoV species. This manipulation leads to the generation of a recombinant, chimeric CoV that may exhibit altered host tropism relative to the parental CoV species. The purpose of these experiments is three-fold:

- Introducing the SARS Spike protein into the backbone of bat CoVs, which do not efficiently infect standard cell culture lines or animals, enables the chimeric virus to infect cells/animals, thus creating a tool that can be used to study the biology of the bat CoV,

- Chimeric viruses are used as tools to test whether CoV therapeutics and vaccines are broad-spectrum, capable of protecting against potentially emerging SARS/MERS-like bat CoVs as well as SARS and MERS, and

- Testing the ability of chimeric CoVs to infect various types of cells and animals reveals the breadth of host tropism conferred by a given Spike protein, and comparing the sequences of

parental and donated Spike proteins with different host tropism can uncover amino acid residues that mediate host restriction.

A second approach that leads to altered host range involves serial passaging of CoVs in mice, which leads to the generation of viruses that have adapted to more efficiently infect and cause disease in mice. The purpose of this experiment is two-fold:

- Mouse-adapted strains are experimental tools that are used for the study of disease pathogenesis and for testing the efficacy and safety of vaccines and therapeutics, and
- Comparing the sequences of the mouse-adapted and the parental strain leads to the identification of mutations that are associated with adaptation, which provides a foundation for follow-up studies investigating the mechanistic basis of virus adaptation to new hosts.

A final approach involves targeted mutagenesis to introduce mutations that are associated with altered host tropism, which is performed to demonstrate that the mutation(s) are necessary and sufficient to alter host tropism. This information provides a foundation for follow-up studies investigating the phenotypic traits underlying virus adaptation to new hosts.

9.3.2.3 Experimental Approaches That Enhance Fitness or Virulence in Cell Culture or Laboratory Animal Model Systems

Several experimental approaches enhance the fitness or virulence of CoVs in cell culture or laboratory animal model systems, respectively. First, serial passaging of CoVs in mice leads to the generation of viruses with both enhanced infectivity to and virulence in mice. Because of the specificity of virus-host interactions that are important determinants of host tropism and pathogenicity, this adaptation often translates to reduced virulence in humans. The purpose of this experiment is two-fold:

- Enhancing the virulence of the virus in mice is an important aspect of creating a mouse model that replicates human disease pathology, which is needed for the study of disease pathogenesis mechanisms and the testing of medical countermeasures, and
- Comparing the sequences of the mouse-adapted and the parental strain leads to the identification of mutations that are associated with enhanced virulence, which provides a foundation for follow-up studies to elucidate the mechanistic basis of virulence. This information can also benefit public health by identifying new potential targets for therapeutics or for attenuation, in order to create attenuated vaccine viruses.

A second approach involves targeted genetic modification of viruses to introduce mutations that are associated with enhanced virulence, which is performed to demonstrate that the mutation(s) are necessary and sufficient to enhance virulence. This information provides a foundation for follow-up studies to elucidate the mechanistic basis of virulence.

A third approach involves serial passaging of attenuated viruses that are candidate live attenuated vaccines, in order to determine whether the viruses acquire mutations that enhance fitness/virulence. Because LAVs with an ability to recover fitness during growth *in vivo* could cause adverse outcomes in people, a negative result is an important indicator of safety for any live attenuated vaccine in development.

9.3.2.4 Experimental Approaches That Lead to Evasion of Therapeutics in Development

Serial passaging of a virus in cells in the presence of a therapeutic may lead to the emergence of viruses that are resistant to inhibition/neutralization by that therapeutic. The purpose of the experiment is to understand whether and how readily resistance will arise in response to selective pressure from the therapeutic and to identify mutations that are associated with resistance to the therapeutic, which provides a foundation for follow-up studies investigating the mechanisms underlying antiviral activity and antiviral resistance. This information benefits the development of these therapeutics. Specifically, emergence-of-resistance data speaks to the potential field efficacy of the therapeutic, and information on both antiviral mechanism and emergence of resistance are important components of an investigational new drug application to the FDA.

9.3.3 Identification of Potential Benefits and Limitations of GoF Research Involving CoVs

In this section, the potential benefits of GoF research involving CoVs in each benefit category listed in the NSABB Framework are evaluated.

9.3.3.1 Benefits and Limitations of GoF to Scientific Knowledge

9.3.3.1.1 Scientific Knowledge Benefit 1: Gain Insight into the Mechanisms Underlying Adaptation of Animal CoVs to Humans

SARS and MERS unexpectedly emerged from their animal reservoirs to infect humans in 2002 and 2012, respectively. Surveillance of bats and other CoV reservoir species indicates that there is a large diversity of animal CoVs circulating in nature, including many species that are genetically related to SARS and MERS and thus may have the potential to spill over into human populations in the future.[483,484,485,486] Although multiple coronaviruses have been shown to exhibit a flexible capacity for cross-species transmission,[487,488] the mechanisms underlying CoV adaptation to new host species are poorly understood.

Several GoF approaches have potential to address this scientific knowledge gap. Serial passaging of CoVs in cells derived from a non-natural host organism or in a non-natural laboratory animal host selects for viruses that more efficiently infect cells/animals, thereby enabling the identification of mutations that are sufficient for adaptation to a new host species. Identifying where mutations arise during adaptation to new hosts points to viral factors that may play a role in adaptation, and studying the phenotypic consequences of the mutations provides insight into the mechanistic basis of cross-species adaptation. One key benefit of this approach is that it can lead to the discovery of novel genetic traits and virus proteins that are involved in the process of adapting to new hosts without the need for prior knowledge of viral adaptation factors. Moreover, this approach can be used to explore the adaptation of any virus to a new host species, provided that the virus can be grown in an appropriate model system. The main limitation of this approach is that laboratory results in cell culture or animal model systems may not translate to viral

adaptation to humans in nature. Additionally, results gleaned from the one or two strains under study may not be conserved in other CoV species.

Another GoF method for studying cross-species adaptation involves "Spike swapping" – that is, targeted genetic modification to replace all or part of the CoV Spike protein, a surface protein that mediates virus entry into cells and is a critical determinant of host restriction, with the Spike protein from another CoV species. These experiments are considered Gain of Function because they are expected to alter host tropism in mammalian species. The purpose of these experiments is two-fold. First, testing the ability of chimeric CoVs to infect various types of cells and animals reveals the breadth of host tropism conferred by a given Spike protein, and comparing the sequences of parental and donated Spike proteins with different host tropism can uncover amino acid residues that mediate host restriction. Second, defining the host tropism of animal CoVs and the number of amino acid changes that are needed to confer the ability to infect human cells provides insight into whether the ability to adapt to new species is a conserved feature of CoVs, as well as which animal CoVs are poised to spill over into human populations. Third, because most bat CoVs cannot be cultured in standard cell culture systems, "Spike swapping" enables the chimeric bat-SARS virus to infect and replicate within human cells, thereby enabling further study of the behavior of the bat CoV. The main drawback of this approach is that it is limited to studying the role of the Spike-receptor interaction in host tropism. Another drawback is that chimeric "SARS plus animal CoV Spike" viruses may behave differently from wild type animal CoVs.

A third GoF approach involves serial passaging of bat CoVs in cell culture, which selects for viruses that are better able to bind, infect, and replicate within human cells (i.e., enhanced pathogen production). For those bat CoVs that can infect cells but grow poorly in cell culture, this enables the development of higher-yield viruses that can be used as tools for the study of bat CoV behavior. Understanding the characteristics of bat CoVs relative to human epidemic CoVs may provide insight into the adaptive changes that facilitate efficient infection of humans.

Finally, targeted genetic modification of wild type viruses to introduce mutations that are associated with adaptation to new hosts demonstrates that such markers are *necessary* and *sufficient* to broaden or alter host tropism. This information provides a strong foundation for follow-up studies investigating the mechanistic basis of the adaptation phenotype.

9.3.3.1.2 Scientific Knowledge Benefit 2: Gain Insight into the Mechanisms Underlying the Pathogenicity of CoVs

Why SARS and MERS coronaviruses cause severe respiratory infections while other human coronaviruses cause mild to moderate illness is unknown.[489] Specifically, the viral genetic and phenotypic traits underlying the enhanced pathogenicity of SARS and MERS relative to other human coronaviruses are poorly understood, and only a few viral virulence factors have been identified and characterized (such as the CoV Spike protein, which mediates viral entry into host cells).

Serial passaging of CoVs in cell culture or laboratory animals, which selects for enhanced fitness (*in vitro*) or enhanced virulence (*in vivo*), is a GoF approach that can yield information that addresses this scientific knowledge gap. This approach enables the identification of mutations associated with enhanced fitness/virulence, which can lead to the discovery of new viral virulence factors and provides a foundation for follow-up studies investigating the mechanistic basis of the enhanced fitness/virulence phenotype observed in emergent viruses. A key benefit of this approach is the ability to generate and identify novel mutations and viral proteins that contribute to fitness/virulence, without prior knowledge about viral virulence factors. Moreover, this approach can be performed with any coronavirus that is capable of

[489] (2015i) Interviews with coronavirus researchers

infecting appropriate cell culture or animal model systems. The main drawbacks of serial passaging experiments are that insights may not translate to human infections, and viral factors and phenotypes that contribute to virulence in the CoV strain under study may not generalize to other CoV strains.

A second GoF approach for studying virulence involves targeted genetic modification of wild type viruses to introduce mutations that are associated with enhanced fitness/virulence, which demonstrates that such markers are *necessary* and *sufficient* to enhance fitness/virulence. This information provides a strong foundation for follow-up studies investigating the mechanistic basis of the enhanced virulence phenotype.

9.3.3.1.3 Scientific Knowledge Benefit 3: Gain insight into Disease Pathogenesis, Including Host Factors That Contribute to Disease Pathology

The host factors involved in SARS and MERS pathogenesis are poorly understood. That is, the contribution of host immune responses to the exacerbated pathology observed during infection with SARS-CoV and MERS-CoV relative to the "common cold" human CoVs is unknown.
Animal-adapted viruses, generated through serial passaging of CoVs in mice to enhance their capacity to infect and cause disease in mice (i.e., altered host range and enhanced virulence) are essential tools for the study of CoV pathogenesis. Infection of mice with animal-adapted viruses recapitulates disease pathology observed during human infection, which is critical for studying the mechanisms underlying disease pathology. Many different experimental methods can be used to study disease pathology using mouse models, including characterizing the host immune response to CoV infection, knocking out or depleting specific host immune factors to probe their role in pathogenesis, and analyzing the tissue tropism and dissemination of CoVs over the course of infection. Of note, mouse-adapted viruses are also important for the study of viral genetic and phenotypic traits that contribute to pathogenesis (scientific knowledge gap 2). The main drawback of using mouse-adapted viruses is that adaptive changes may alter the biology of the virus, such that findings are mis-representative of wild type virus behavior.

9.3.3.2 Benefits and Limitations of GoF to Surveillance

Currently, GoF approaches do not have the potential to benefit public health, agricultural animal, or wildlife surveillance. Although CoV researchers stated that they could envision using information about the molecular determinants of human adaptation and virulence to assess the risk posed by animal CoVs circulating in nature, similar to the influenza field, this application is currently unfeasible for two reasons: (1) CoV surveillance networks are extremely limited, with large gaps in coverage in humans and animals, and (2) the state of knowledge about the molecular determinants of human adaptation and virulence is poor.[490]

9.3.3.3 Benefits and Limitations of GoF to Vaccine Development

Currently, there are no FDA-approved vaccines for CoVs, which represents a critical gap in public health preparedness for CoV outbreaks. Several GoF approaches have the potential to benefit the development of new CoV vaccines.

9.3.3.3.1 Vaccine Development Benefit 1: Developing Vaccine Candidates

GoF approaches have the potential to benefit two aspects of the development of live attenuated vaccine (LAV) platforms, which is a type of vaccine that is being actively researched for its potential as a CoV vaccine platform. First, GoF approaches can inform the development of candidate LAV strains, which exhibit attenuated virulence relative to parental strains. Specifically, one strategy for generating LAV

[490] For example, out of more than 1700 bat species, only ten have been surveilled for evidence of CoV infection (and those ten on an ad hoc rather than a systematic basis).

strains is through serial passaging in a non-human host (either an animal or cells derived from an animal), as adapting a virus to a new host typically attenuates the virus in humans (i.e., alters rather than enhances host tropism). Because this approach **alters host tropism**, it is considered to be a GoF approach under the NSABB Framework. Although serial passaging has been used historically for developing polio, smallpox and other viral vaccines, the approach has not been utilized for the purpose of developing CoV vaccine strains.[491] Alternatively, live attenuated vaccines can be generated through targeted mutagenesis to attenuate or knock out the function of known virulence factors. As described above (Section 9.3.3.1.2), GoF studies that **enhance virulence** represent the most efficient and effective strategy for identifying novel CoV virulence factors, which may be good targets for attenuation to develop an LAV. However, follow-up studies are needed to determine how to attenuate that factor or to render it non-functional.

LAVs are an appealing type of vaccines for CoVs for several reasons, and multiple LAV candidates for SARS have been shown to protect against lethal virus challenge in mice, demonstrating the promise of this type of vaccine for CoVs.[492,493] However, a major concern is their potential to regain virulence in people, which necessitates stringent safety testing of all LAV candidates.

9.3.3.3.2 Vaccine Development Benefit 2: Determining the Potential for LAVs to Recover Virulence

Once a candidate LAV strain has been generated, the strain is typically serially passaged *in vitro* or *in vivo* to determine whether the virus recovers fitness/virulence (i.e., **enhanced fitness/virulence**). Because a tendency to revert or acquire compensatory mutations that enhance fitness/virulence could seriously compromise the safety of a live attenuated vaccine, demonstrating the genetic stability of a candidate LAV is a critical aspect of its development.

9.3.3.4 Benefits and Limitations of GoF to Therapeutic Development

Currently, there are no FDA-approved therapeutics for CoVs, which represents a critical gap in public health preparedness for CoV outbreaks. Several GoF approaches have the potential to benefit the development of new CoV therapeutics.

9.3.3.4.1 Therapeutic Development Benefit 1: Developing Candidate Therapeutics

CoV researchers cited the lack of knowledge of good viral targets for therapeutics as a critical limitation for the development of CoV therapeutics.[494] GoF approaches currently represent the most efficient and effective way to identify novel virulence factors and gain insight into their mechanism of activity, a foundation for the development of antivirals (see Section 9.3.3.1.2). However, whether inhibiting or attenuating the virulence factor is sufficient to reduce viral replication and infection-associated pathology must be determined through alternative approaches.

9.3.3.4.2 Therapeutic Development Benefit 2: Generating Nonclinical Data to Support an Investigational New Drug Application to the FDA

The first step in the licensure process for new drugs involves submission of an Investigational New Drug (IND) application to the FDA's Center for Drug Evaluation and Research (CDER). CDER recommends that several types of nonclinical studies are conducted before starting Phase I clinical studies, including

492 Graham RL *et al* (2012) A live, impaired-fidelity coronavirus vaccine protects in an aged, immunocompromised mouse model of lethal disease. *Nature medicine* 18: 1820-1826

493 Fett C *et al* (2013) Complete protection against severe acute respiratory syndrome coronavirus-mediated lethal respiratory disease in aged mice by immunization with a mouse-adapted virus lacking E protein. *Journal of virology* 87: 6551-6559

494 (2015i) Interviews with coronavirus researchers.

determination of the drug's mechanism of action, *in vitro* selection of resistant viruses to the investigational product, and the genotypic and phenotypic characterization of resistant viruses.[495] GoF approaches that lead to evasion of therapeutics generate information that fulfills both of those recommendations, thereby supporting the licensure of new therapeutics.

First, serial passaging of viruses in the presence of a therapeutic to select for resistant viruses, followed by sequencing of the emergent resistant strains to identify genetic changes that arose, can provide insight into the mechanism of action of the therapeutic. Understanding which viral protein or proteins mutate in order for the virus to escape inhibition suggests those proteins are targeted by the therapeutic, and the site and phenotypic consequences of the mutations may provide insight into the mechanism of antiviral activity. Together, this information provides a foundation for follow-up structural, biochemical, and cell biological assays investigating the mechanism of antiviral activity. Second, this approach directly fulfills FDA's recommendation for *in vitro* selection of resistant viruses, which is performed to determine the genetic threshold for the development of resistance (i.e., the number of mutations that are needed for a virus to acquire resistance).

9.3.3.4.3 Therapeutic Development Benefit 3: Determining the Therapeutic Dosage and/or Combination Therapies That are Least Likely to Lead to the Emergence of Resistance

GoF studies that lead to evasion of therapeutics can also inform the therapeutic dosage and the use of combination therapies, both of which influence whether and how readily antiviral resistance arises. Specifically, serial passaging of virus in animals dosed with varying amounts of the therapeutic provides insight into the dosage that is least likely to lead to the emergence of resistant viruses, and serial passaging of virus in cells or in animals in the presence of multiple mAbs (or other types of therapeutics) can be used to determine how readily resistance arises in response to combination versus single therapies. This information may lead to the development of therapeutic strategies that will be effective for a longer period of time in the field.

9.3.3.5 Benefits and Limitations of GoF to Both Vaccine and Therapeutic Development

9.3.3.5.1 Vaccine/Therapeutic Development Benefit 1: Testing the Safety and Efficacy of MCM Candidates

The use of animal-adapted viruses, generated using GoF approaches that **alter host range** and **enhance virulence**, facilitate MCM development by enabling the testing of MCM candidates in an animal model that mimics the pathology of human disease. Animal-adapted strains represent a robust system for demonstrating that a candidate MCM is capable of preventing or reducing disease-associated pathology. In addition, the use of models that share features of human disease can reveal adverse side effects of the vaccine and thus is an important aspect of safety testing prior to the initiation of human clinical trials.

9.3.3.5.2 Vaccine/Therapeutic Development Benefit 2: Developing Broad-Spectrum Vaccines

Finally, GoF approaches that **alter host range** inform the development of broad-spectrum vaccines that may be capable of protecting against the next emerging CoV. Specifically, chimeric bat-SARS viruses can be used as challenge viruses to explore the broad-spectrum potential of candidate MCMs, in order to test whether MCMs designed to target SARS/MERS proteins are also capable of targeting cognate proteins in bat CoVs as well as whether vaccines can target SARS/MERS proteins in a different virus

[495] Food and Drug Administration. Guidance for Industry: Antiviral Product Development - Conducting and Submitting Virology Studies to the Agency. http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM070953.pdf. Last Update June 2006. Accessed 14 October 2015.

context (representative of the next emerging CoV capable of infecting humans). These experiments can provide insight into whether MCMs targeting any CoV protein or process are capable of conferring broad-spectrum protection against bat CoVs with zoonotic potential, in addition to SARS and MERS.

9.3.3.6 Benefits and Limitations of GoF to Diagnostic Development

As diagnostic targets for CoVs are well-established, potential benefits of GoF approaches to the development of diagnostics were not identified.[496, 497,498, 499]

9.3.3.7 Benefits and Limitations of GoF to Decision-Making in Public Health Policy

Because the US government is not actively engaged in public health preparedness activities for CoV outbreaks and because there are no FDA-approved vaccines or therapeutics for CoVs, GoF approaches do not have the potential to benefit decision-making in public health policy (e.g., informing countermeasure stockpiling decisions, guiding decisions about strain selection for vaccine development, etc.)

9.3.3.8 Economic Benefits

GoF benefits to the development of vaccines and therapeutics could have downstream economic benefits. Economic benefits were not explicitly evaluated in this report.

9.3.4 Identification of Alt-GoF That Provide Similar Potential Benefits to the GoF Being Examined

In this section, an overview of alternative (alt-GoF) approaches that yield the same or similar benefits as the GoF approaches described above is provided. Two types of alt-GoF approaches are reviewed: (1) alternative experimental approaches that can provide the same or similar scientific information as GoF experimental approaches, and (2) alternative scientific and technical innovations that can yield the same public health benefits as GoF approaches but through different mechanisms, including the use of alternative model systems that do not rely on GoF approaches. For each approach, the scientific outcomes or products of the approach are first described, then how that information or products leads to similar benefits as GoF approaches.

9.3.4.1 Benefits and Limitations of Alt-GoF Approaches to Scientific Knowledge

9.3.4.1.1 Scientific Knowledge Benefit 1: Gain Insight into the Mechanisms Underlying Adaptation of Animal CoVs to Humans

Several alternative experimental approaches can be used to discover genetic traits associated with cross-species adaptation of CoVs.

---

[496] The FDA-approved diagnostic test for MERS-CoV targets two regions in the CoV genome: a region upstream of the E gene (*upE*) and the reading frame 1a (*orf1a*). SARS can be detected through RT-PCR with sequences in the polymerase 1 B region (*pol* 1B) and an adjacent downstream region of the genome as the targets. Other diagnostic tests target sequences in the nucleocapsid (N) gene.

[499] Mahony JB *et al* (2004) Performance and Cost evaluation of one commercial and six in-house conventional and real-time reverse transcription-pcr assays for detection of severe acute respiratory syndrome coronavirus. *J Clin Microbiol* 42: 1471-1476

Comparing the sequences of CoVs with different species tropism, including comparison of animal CoVs versus SARS/MERS and comparison of animal strains from different geographic regions where spillover into human populations has and has not occurred (or has occurred with different frequencies), can elucidate genetic traits that are associated with adaptation to different hosts. Second, comparative sequence analysis of human CoVs from different time points during an outbreak reveals how zoonotic CoVs adapt to humans following an initial spillover event. Relative to the laboratory methods described above, this approach has potential to identify traits that are relevant for adaptation to humans under natural selective pressures. Importantly, follow-up studies are needed to confirm that the identified genetic traits are responsible for altered host tropism.

Both types of comparative sequence approaches suffer from several significant limitations. First, the success of comparative sequence analysis is significantly constrained by the quality and availability of existing genetic surveillance data. A second limitation is that, due to the large size of the CoV genome (27-32 kb) and the genetic diversity of coronaviruses in nature, there are a very large number of genetic differences between any two CoV strains, only a subset of which are likely to be important for cross-species adaptation.[500] Because of that "noise," sequence comparisons are realistically limited to known regions of interest, precluding discovery of novel factors that are involved in host adaptation. Due to the fact that only a few proteins have been shown to be involved in cross-species adaptation and the function of most CoV proteins is unknown, this limited focus represents a critical shortcoming of the comparative sequence analysis approach. Although this limitation could be partially addressed by comparing sequences of paired animal and human isolates, few such paired sequences are available. Third, this approach is reactive, limited to the study of mechanisms underlying adaptation of CoVs that have already evolved to broaden or alter their host tropism (e.g., SARS and MERS). The mechanisms driving adaptation of other CoVs to new hosts may be different.

Several alternative approaches seek to define the breadth of host tropism conferred by a given Spike protein. The first approach involves testing whether MERS- or SARS-CoVs can infect cells derived from various non-human host species such as bats or cells that do not naturally express CoV receptor proteins but have been engineered to ectopically express receptor proteins from various species. This approach cannot be used for most animal CoVs, which cannot be grown efficiently in cell culture to produce infectious material for laboratory assays. Alternatively, two virus-free approaches can provide information about compatible Spike-host interactions: (1) *in vitro* binding assays using recombinant Spike proteins and host receptor proteins from different species, and (2) cell culture-based binding and virus entry assays using non-CoVs (e.g., murine leukemia virus) that are pseudotyped with CoV Spike proteins. (Pseudotyping is the process of expressing the envelope protein or surface glycoprotein from one virus on the surface of a different virus, e.g., replacement of the vesicular stomatitis virus glycoprotein (VSV G) with the CoV Spike, enabling expression of the CoV Spike on the surface of VSV.) These *in vitro* systems can also be used to confirm that amino acid substitutions in the Spike protein are necessary and sufficient to alter host receptor binding and cell entry capabilities. The major limitation associated with these virus-free approaches is that results may not be recapitulated in the context of the wild type virus, as the virus context influences presentation of surface epitopes. Additionally, results from either virus-free approach may not be conserved in a different strain context, and traits that promote binding of pseudotyped viruses to a particular cell type may not be critical for adaptation to human hosts. Finally, these approaches are currently used to investigate the role of the Spike-receptor interaction in host restriction only.

---

[500] Graham RL, Baric RS (2010) Recombination, reservoirs, and the modular spike: mechanisms of coronavirus cross-species transmission. *Journal of virology* 84: 3134-3146

Finally, structural modeling of Spike-receptor interactions, based on crystal structures of Spike-receptor complexes, can also be used to identify amino acid residues in the Spike protein that may be important determinants of host restriction. Though useful for generating hypotheses about mutations that may alter host tropism, all predictions must be experimentally confirmed.

In addition to the use of serially-passaged bat CoVs or chimeric CoVs, several alternative model systems can be used to study the biology of bat CoVs, which may provide insight into the adaptive changes that are needed for CoVs to efficiently infect humans. First, some bat CoVs are naturally capable of replicating within bat cell lines or other standard cell culture systems. However, bat cell lines are much less experimentally tractable than human cell lines, as fewer reagents are available and the cells are more difficult to transfect than human cells, further lessening the utility of this approach.[501,502] Second, host cells that are not naturally permissive to infection with animal CoVs can be sensitized to infection through ectopic expression of the receptor protein from the natural host species (or another permissive host species). This approach has been utilized for a limited number of CoVs, and whether it will permit replication of a broad range of emerging CoVs is unknown. Furthermore, this strategy cannot be used for primary cell lines, which are not readily transfectable, and overexpression of the receptor may alter the process of infection, leading to artefactual results.

9.3.4.1.2 Scientific Knowledge Benefit 2: Gain Insight into the Mechanisms Underlying the Pathogenicity of CoVs

Several alternative approaches can also be used to study pathogenicity. Comparative sequencing of SARS-CoV and MERS-CoV epidemic strains with varying levels of virulence can lead to the identification of mutations associated with enhanced virulence. A strength of this approach relative to serial passaging is that comparative sequence analysis uncovers genetic variation that is specially associated with enhanced virulence in humans.[503,504] However, this approach is limited to CoVs that have already produced epidemics in humans, i.e., SARS-CoV and MERS-CoV. The success of this approach is constrained by the quality and availability of surveillance data, in particular the quality of "metadata" about clinical severity that is needed to "bin" sequences into low- and high-virulence categories for comparison. While SARS-CoV strains from the early, middle, and late phases of the 2002 – 2003 epidemic have been found to exhibit varying levels of virulence (and have been used for comparative sequence analysis studies), genetic surveillance data for MERS are limited. Finally, given the large size of the CoV genome and genetic diversity among wild type CoV sequences, sequence comparisons are practically limited to pre-determined regions of interest, which precludes identification of novel virulence factors.

A second sequence-based approach involves analyzing the evolution of CoVs over time. Understanding which regions of the genome mutate and which do not can provide insight into which regions are likely to be critical for the virus life cycle, which may or may not contribute to pathogenicity. However, the utility of this approach is also limited by the number of available CoV sequences.

Loss of Function (LoF) studies, which involve knocking out or otherwise hampering the function of a gene of interest (or its product) and screening for attenuated fitness (*in vitro*) or virulence (*in vivo*), represent another alternative approach for the discovery of viral virulence factors and genetic traits

503 de Jong MD *et al* (2005) Oseltamivir Resistance during Treatment of Influenza A (H5N1) Infection. *New England Journal of Medicine* 353: 2667-2672

504 Chinese SMEC (2004) Molecular evolution of the SARS coronavirus during the course of the SARS epidemic in China. *Science* 303: 1666-1669

associated with virulence. Given the large size of the CoV genome, a random mutagenesis approach is practically limited to the investigation of known virulence factors. A targeted gene knockout strategy can be used to identify new viral genes that contribute to virulence, but a limited number of mutants can be screened for attenuated virulence *in vivo*, due to the labor, expense, and ethical considerations associated with the conduct of animal experiments. Thus, high-throughput screening of gene knockout viruses is limited to screening for attenuated fitness in cell culture systems, which is only one aspect of virulence. The major drawback of LoF screens is that losing the functionality of a virus protein, either through gene knockout of mutagenesis, may indirectly attenuate virulence, so that gaining meaningful information about virulence mechanisms may be difficult using this approach. Finally, it is noted that knocking out the function of an unknown viral protein can lead to a loss or gain of virulence, depending on the function of the protein.

LoF approaches can also be used to confirm that a particular trait is *necessary* for enhanced virulence. However, because virulence is a complex, multi-genic trait, knocking out the function of one gene or introducing a mutation into one gene may be sufficient to attenuate virulence but provides an incomplete picture of the role of that particular protein. Additionally, mutations that are found to enhance virulence in model systems may not translate to increased virulence during human infections.

9.3.4.1.3 Scientific Knowledge Benefit 3: Gain Insight into Disease Pathogenesis, Including Host Factors That Contribute to Disease Pathology

In addition to using animal-adapted viruses generated through GoF approaches, several alternative model systems can be used to study disease pathogenesis.

Naturally susceptible laboratory animals represent one alternative model system for studying disease pathogenesis. However, laboratory animals that are naturally susceptible to infection with SARS-CoV and MERS-CoV have been found to support viral replication but remain asymptomatic or develop symptoms dissimilar to those in humans. Thus, these animal models are not suitable for pathogenesis studies.

Use of transgenic animals expressing the human virus receptor is another alternative to the use of adapted viruses for hosts that are not permissive to infection or do not recapitulate human disease pathology. A variety of approaches have been used to create transgenic mouse models for SARS-CoV and MERS-CoV infection, and each technique results in a slightly different gene expression pattern and reproduces human disease symptoms to a different degree. The ability to infect transgenic mice with wild type SARS-CoV and MERS-CoV is a strength of this model system. However, given differences in pathogenesis, results may not translate to human disease.

Finally, human autopsy data can be an alternative source of pathogenesis information. However, the availability of these data are limited – autopsies are not often performed in Middle Eastern cultures, and data has not yet been shared from the most recent outbreak in the Republic of Korea.[505] Furthermore, analysis of human autopsy data provides limited mechanistic insight because it is inherently correlative and is devoid of time series information, obscuring the order in which pathogenic effects occurred. Additionally, insights gleaned from the study of severe, end-stage disease may not be representative. The fact that many SARS-CoV and MERS-CoV deaths occurred in patients with pre-existing conditions further complicates the identification of pathology caused by viral infection versus comorbidities.

[505] (2015i) Interviews with coronavirus researchers.

9.3.4.2 Benefits and Limitations of Alt-GoF Approaches to Vaccine Development

9.3.4.2.1 Vaccine Development Benefit 1: Developing Vaccine Candidates

Live attenuated vaccines (LAVs) may be generated through targeted mutagenesis to knock out or attenuate the function of known virulence factors. LoF approaches, namely screening of gene knockout viruses or randomly mutagenized viruses for attenuated virulence, are relatively inefficient for the discovery of novel virulence factors but can be used to confirm that inhibiting or attenuating the function of a virulence factor is sufficient to attenuate virus replication.

In addition to LAVs, several other types of CoV vaccines are in development, which do not rely on GoF approaches for their initial development. Alternative vaccine platforms of interest include inactivated whole virus vaccines, recombinant vaccines, DNA vaccines, viral vector-based vaccines, and virus-like particles (VLPs).[506] Many of these vaccine types have shown promise, and each has strengths and limitations relative to the use of live attenuated vaccines.

9.3.4.2.2 Vaccine Development Benefit 2: Determining the Potential for LAVs to Recover Virulence.

There are no alternative approaches for determining the potential for LAVs to recover virulence upon growth in cells or animals prior to the clinical testing of vaccine candidates in people.

9.3.4.3 Benefits and Limitations of Alt-GoF Approaches to Therapeutic Development

9.3.4.3.1 Therapeutic Development Benefit 1: Developing Candidate Therapeutics

Several alternative approaches can inform the development of candidate therapeutics against CoVs. First, LoF approaches can lead to the identification of novel virulence factors, which may be good targets for new therapeutics. LoF approaches are relatively inefficient for the discovery of novel virulence factors but are critical for demonstrating that inhibition or attenuation of a virulence factor is sufficient to reduce viral replication or infection-associated pathology.

An alternative approach to the targeted development of therapeutics involves high-throughput screening of compounds for their ability to reduce viral replication *in vitro*.[507,508,509,510,511] This is also an active area of therapeutic research in the CoV field and has generated several promising candidates. One drawback of this approach is that it is limited to the identification of compounds that reduce viral replication, which is only one aspect of virulence. Targeting other aspects of virulence, such as viral interactions with the host immune system, may prove to be a more effective therapeutic strategy.

A related alternative approach involves high-throughput screening of panels of monoclonal antibodies (mAbs) to identify mAbs that bind to CoV Spike proteins, as mAbs targeting the Spike protein have been shown to effectively prevent viruses from infecting cells and could prime the immune system to clear the infection.[512] One potential drawback of this therapeutic strategy is that CoVs can readily acquire mutations in their Spike protein that enable escape from mAb neutralization; however, researchers are actively pursuing the development of "cocktails" of mAbs that are more robust to the generation of escape mutants.[513,514] Additional drawbacks are that antibody-based therapeutics, which are uncommon for infectious diseases, may only slow infections and must be injected because antibodies are not small molecules.

9.3.4.3.2 Therapeutic Development Benefit 2: Generating Nonclinical Data to Support an Investigational New Drug Application to the FDA

Several alternative approaches can be used to investigate the mechanism of activity of a new therapeutic candidate. First, high-throughput RNAi screens targeting host proteins can identify host proteins that are required for the drug's mechanism of action, by demonstrating that knockdown of a particular host protein impedes the drug's ability to inhibit viral replication. Though an informative strategy for the study of therapeutics targeting host proteins, high-throughput RNAi screens provide minimal information about potential viral targets of therapeutics. (It should be noted that this approach is typically performed to identify the potential targets of drugs identified through high-throughput screens, as the candidate drugs may attenuate viral replication by directly targeting viral proteins or by indirectly targeting host proteins.)

If the therapeutic target of a drug is known, analyzing the crystal structure of the viral target in complex with the antiviral compound (or mAb) can provide insight into the compound's mechanism of activity.[515,516] This approach is particularly useful for therapeutics that directly bind to and inhibit the activity of a viral protein. Though X-ray crystallography is appealing for its potential to provide direct information about the interaction between an antiviral and its target, inferring how that interaction affects a process in the viral life cycle may be difficult from such a static snapshot. Critically, because of the high level of effort required for X-ray crystallography, it is not a feasible approach for simply screening the potential viral targets of an unknown antiviral.

Photoaffinity cross-linking represents an alternative approach for identifying the binding site of a drug with a known target. This technique shares strengths and weaknesses with X-ray crystallography. Namely, photoaffinity cross-linking is useful for small molecule drugs that directly bind to and inhibit the activity of a viral protein and does not require prior knowledge of the location of the drug binding site.[517] However, inferring the mechanism of antiviral activity based on knowledge about the drug-virus protein interaction may be difficult.

There are no alternative approaches that can determine the genetic threshold for resistance to a new therapeutic, which is a recommended piece of data to support an Investigational New Drug (IND)

application to the FDA, prior to deployment of the therapeutic and the emergence of resistant viruses in nature.

9.3.4.3.3 Therapeutic development benefit 3: Determining the therapeutic dosage and/or combination therapies that are least likely to lead to the emergence of resistance

No alternative approaches are capable of providing information about the dose-dependence of resistance or whether combination therapies lead to resistance less readily than individual therapies, prior to clinical testing or post-marketing studies.

9.3.4.4 Benefits and Limitations of Alt-GoF Approaches to Both Vaccine and Therapeutic Development

9.3.4.4.1 Vaccine/Therapeutic Development Benefit 1: Testing the Safety and Efficacy of MCM Candidates

In addition to animal-adapted viruses, several alternative model systems could be used to test the safety and efficacy of vaccine candidates, namely naturally susceptible hosts and transgenic animals (see Section 9.3.4.1.3). Transgenic mice are important in countermeasure development because they can be used to establish that a therapy knocks down virus titers in a system with human receptors.[518] However, the predictive value of safety and efficacy data gleaned from experiments using transgenic animals is constrained by the fact that transgenic animals do not fully recapitulate human disease pathogenesis. Naturally susceptible hosts of SARS or MERS are either asymptomatic or develop symptoms dissimilar to those in humans. As a result, these "replication" models have limited utility for advanced vaccine development. Replication models may provide easy metrics to demonstrate vaccine or drug efficacy (i.e., reduction in viral replication), but their lack of relevant symptomology could lead to the development and release of subpar or dangerous countermeasures. Specifically, therapeutics may cause unintended side effects or deleterious interactions with the host immune system, which are unpredictable and may not be observed in asymptomatic animal models.

9.3.4.4.2 Vaccine Development Benefit 4: Developing Broad-Spectrum Vaccines

In addition to chimeric bat-SARS viruses generated through GoF approaches, several alternative model systems can be used to evaluate the broad-spectrum potential of candidate MCMs. One approach involves the use of wild type bat CoVs as challenge viruses, in lieu of chimeric bat-SARS viruses. However, the fact that few bat CoVs can be grown in culture or in animals without the use of GoF approaches (serial passaging or the generation of chimeric viruses) diminishes the utility of this approach.
For evaluating MCMs that target the Spike protein, the use of pseudotyped viruses represents another alternative approach. Because Spike proteins are presented differently in the context of pseudotyped viruses versus CoVs, results using pseudotyped viruses may not be recapitulated in the context of the wild type virus.[519] Thus, all results using pseudotyping systems must be confirmed using wild type viruses (or chimeric CoVs, which better mimic wild type bat CoVs than pseudotyped viruses). Finally, chimeric viruses that have been engineered to express "internal" (i.e., non-Spike) CoV proteins have been used for testing the efficacy of therapeutics targeting non-Spike proteins.[520] As with pseudotyped viruses, due to significant differences in the course of infection between chimeric virus systems and wild type viruses, such chimeric virus systems can be used to screen therapeutic candidates but do not replace the need to test MCMs against the wild type virus.

9.3.5 Comparison and Analysis of the Potential Benefits of GoF Approaches Versus Alt-GoF Approaches

9.3.5.1 Benefits to Scientific Knowledge

9.3.5.1.1 Scientific Knowledge Benefit 1: Gain Insight into the Mechanisms Underlying Adaptation of Animal CoVs to Humans

Serial passaging, a GoF approach that alters host range, is **uniquely capable** of identifying *novel* viral genetic traits and factors that contribute to cross-species adaptation. Moreover, to elucidate the molecular mechanisms underlying the role of the Spike-receptor interaction in host adaptation, testing the phenotypic consequences of mutations in animal CoV Spike proteins in the context of a chimeric virus generated through GoF approaches provides a higher level of certainty in the validity of the results than similar confirmatory experiments using recombinant proteins or pseudotyped viruses. However, sequence comparisons, an alt-GoF approach, are uniquely capable of identifying genetic traits that are associated with mammalian adaptation across a variety of strains as well as discovering genetic markers that are definitively associated with human adaptation. However, the causality of markers identified through sequence analysis must be confirmed with a GoF experiment, and the utility of the comparative sequence approach is severely compromised by the poor state of genetic surveillance for CoVs in human and animal populations and the fact that it is limited to analysis of strains that have caused human infections.

In addition to the approaches described above, characterizing SARS/MERS-like animal CoVs, thought to be precursors for SARS/MERS or to have similar potential to spill over into human populations, also provides insight into how SARS and MERS emerged from their animal reservoirs to infect humans. However, most animal CoVs grow poorly, if at all, in standard cell culture systems. GoF approaches have **unique potential** to enable the development of *in vitro* model systems for the study of any animal CoV in a variety of cell types, including immortalized cell lines and relevant primary cell lines such as human epithelial airway cells. Alternatives to GoF have significant shortcomings. Only a subset of animal CoVs identified to date can be cultured in bat, human, or other standard cell lines, limiting the utility of using naturally permissive cell lines for *in vitro* studies. While ectopic expression of permissive receptor proteins in a common cell line has been shown to permit replication of several CoVs, this strategy is limited to cell lines that can be readily transfected (i.e., not primary cell lines) and overexpression of the host receptor may alter the biology of infection, limiting the relevance of results from this system.

9.3.5.1.2 Scientific Knowledge Benefit 2: Gain Insight into the Mechanisms Underlying the Pathogenicity of CoVs

Serial passaging for the selection of CoV strains with enhanced pathogenicity in animals or fitness in cell culture, a GoF approach, is the most efficient and effective method for identifying novel genetic traits and/or viral factors that contribute to virulence in any coronavirus strain. The alternate approaches have several drawbacks. While screening gene knockout viruses *in vitro* represents a viable approach for the discovery of novel virulence factors, this LoF approach is limited to the identification of proteins that influence replicative fitness, only one component of virulence, and may uncover factors that attenuate virulence for trivial reasons. The main drawback of both the GoF and LoF approaches is that insights gleaned from model systems may not translate to human infection. To that end, comparatively analyzing the sequences of SARS/MERS strains with varied levels of virulence can provide direct insight into genetic traits that are associated with pathogenicity in humans. However, this approach is limited to the study of SARS and MERS and is significantly constrained by shortcomings in the quality and availability of existing genetic surveillance data. In addition, any hypothesis generated through comparative sequence analysis must be experimentally confirmed. The phenotypic consequences of mutations that are associated with enhanced virulence can be validated using GoF approaches, which are uniquely capable

of demonstrating that mutations are necessary and sufficient to enhance virulence, or LoF approaches, which can demonstrate that mutations are necessary for enhanced virulence only. Complex, multi-genic traits such as virulence are difficult to tease apart using solely LoF approaches because LoF provides limited information about how proteins cooperate to enhance virulence. However, because the value of the information gleaned from both LoF and GoF approaches depends on the relevance of artificially manipulated viruses to nature, using both approaches to confirm the role of a particular mutation or phenotype strengthens any conclusion.

9.3.5.1.3 Scientific Knowledge Benefit 3: Gain Insight into Disease Pathogenesis, Including Host Factors That Contribute to Disease Pathology

Mouse-adapted strains of SARS, which exhibit altered host range and enhanced virulence in mice relative to the wild type SARS virus, represent the only model system that recapitulates disease pathogenesis observed during human infections of SARS-CoV. As existing animal models for MERS-CoV do not replicate human disease pathology, mouse-adapted strains of MERS-CoV are expected to serve as the sole pathogenesis model for the study of MERS-CoV infection as well. As such, animal-adapted strains can be used to study many facets of disease pathogenesis, including the course of disease, the role of viral and host immune factors in disease pathology, and the role of tissue tropism in disease pathology. Alternative model systems have critical drawbacks for the study of disease pathogenesis. Because transgenic animals do not recapitulate the features of human disease, lessons learned about pathogenesis may not translate to humans. Most naturally susceptible hosts are asymptomatic or display dissimilar symptoms to humans and thus cannot be used to study disease pathogenesis. While human autopsy data are uniquely capable of providing insight into human disease pathology, limited autopsy data are available, and the static nature of the data and the presence of co-morbidities in many SARS/MERS patients complicate interpretation of that data.

9.3.5.2 Benefits to the Development of Vaccines

9.3.5.2.1 Vaccine Development Benefit 1: Developing Vaccine Candidates

Live attenuated vaccines (LAVs) are being actively researched for their potential as CoV vaccine platforms. GoF approaches that enhance virulence represent the most efficient and effective strategy for identifying CoV virulence factors, which may be good targets for attenuation. LoF approaches are relatively inefficient for the discovery of novel virulence factors but are critical for demonstrating that mutagenesis or knockout of a particular virulence factor is sufficient to attenuate viral replication, the goal of generating an LAV candidate.

LAVs are an appealing type of vaccine for CoVs for several reasons, and multiple LAV candidates for SARS have been shown to completely protect against lethal virus challenge in mice, demonstrating the promise of this type of vaccine for CoVs.[521,522] However, one significant concern associated with LAVs is their potential to regain virulence in people. Several other types of CoV vaccines are in development, which do not rely on GoF approaches, and many have shown promise in animal models. Each alternative vaccine type has strengths and weaknesses relative to LAVs, and the type or types of vaccines that will ultimately prove to be most effective for SARS, MERS, and SARS/MERS-like coronaviruses are not yet clear based on vaccinology research conducted to date.[523] Given the need for CoV vaccines, pursuing all

[523] Zhang N *et al* (2014) Current advancements and potential strategies in the development of MERS-CoV vaccines. *Expert Rev Vaccines* 13: 761-774

promising strategies for vaccine development in tandem, including LAVs, will ensure that an effective vaccine is achieved in the shortest possible period of time.

9.3.5.2.2 Vaccine Development Benefit 2: Determining the Potential for LAVs to Recover Virulence.

GoF approaches, namely serial passaging of LAVs in cells or animals, **are uniquely capable** of determining whether a candidate LAV will recover fitness/virulence upon growth in cells or animals. Because a tendency to revert or acquire compensatory mutations that enhance fitness/virulence could seriously compromise the safety of a live attenuated vaccine, demonstrating the genetic stability of a candidate LAV is a critical aspect of its development.

9.3.5.3 Benefits to the Development of Therapeutics

9.3.5.3.1 Therapeutic Development Benefit 1: Developing Candidate Therapeutics

As described above (Section 9.3.5.1.1), GoF approaches represent the most efficient and effective strategy for identifying novel CoV virulence factors, which may serve as good therapeutic targets. However, follow-up studies are needed to develop therapeutics that inhibit the function of that virulence factor and to determine whether blocking its function is sufficient to reduce disease-associated pathology and/or viral shedding. High-throughput screening of small molecule compounds for their ability to block viral replication *in vitro* has generated several promising therapeutic candidates but is limited to the discovery of therapeutics that inhibit viral replication, which is only one aspect of virulence. Several research groups are pursuing the development of monoclonal antibodies targeting the CoV Spike protein, as mAb binding has been shown to inhibit the ability of the virus to bind and infect cells, but mAb-based therapeutics suffer several drawbacks relative to small molecule drugs and other types of therapeutics. As for CoV vaccines, the type or types of therapeutics that will ultimately prove to be effective against CoVs is not yet clear based on current research. Given the need for CoV therapeutics, pursuing all promising strategies for therapeutic development in tandem will ensure that an effective therapeutic is achieved in the shortest possible period of time.

9.3.5.3.2 Therapeutic Development Benefit 2: Generating Nonclinical Data to Support an Investigational New Drug Application to the FDA

Serial passaging of a virus in the presence of therapeutic to discover mutations that confer resistance, a GoF approach, is **uniquely capable** of identifying the viral target of a novel therapeutic with an unknown mechanism of action. For therapeutics with known viral targets, this information about resistance mutations can provide foundational information to guide follow-up structural, cell biological, and biochemical studies investigating the mechanism of action of the therapeutic. Although crystallography and photoaffinity cross-linking can also provide insight into the antiviral mechanisms of therapeutics that directly bind to and inhibit virus proteins, inferring mechanistic information based on static information about the virus-antiviral complex may be difficult. Finally, the identification of host factors that are required for antiviral activity is a critical aspect of examining therapeutics with unknown targets but provides limited mechanistic information about therapeutics that target virus proteins.

Additionally, serial passaging of viruses in the presence of therapeutic is uniquely capable of determining the genetic threshold for resistance development prior to deployment of the therapeutic and the emergence of resistant strains in nature.

As both mechanism of action and selection for resistance studies to determine the genetic threshold for resistance development are recommended components of an Investigational New Drug application to the

FDA, GoF approaches that lead to the generation of viruses that are resistant to therapeutics in development are **essential** for the licensing of new therapeutics.

9.3.5.3.3 Therapeutic Development Benefit 3: Determining the Therapeutic Dosage and/or Combination Therapies that are Least Likely to Lead to the Reemergence of Resistance

GoF approaches that lead to the generation of viruses that are resistant to therapeutics in development are **uniquely capable** of determining the therapeutic dose that is least likely to lead to the acquisition of antiviral resistance as well as determining whether combination therapies better prevent the emergence of resistant viruses than individual therapies. Both types of information benefit the development of therapeutic strategies that will be effective for a longer period of time in the field.

9.3.5.4 Benefits to the Development of Vaccines and Therapeutics

9.3.5.4.1 Vaccine/Therapeutic Development Benefit 1: Testing the Safety and Efficacy of MCM Candidates

The use of animal-adapted strains of CoVs is critical for advanced MCM development as well and provides significant advantages over the use of alternative model systems. Though transgenic animals and naturally susceptible hosts can be used to demonstrate that MCMs diminish viral replication, an important proof of concept for early stage MCMs, animal-adapted strains that replicate human disease pathology provide a much more robust system for demonstrating the safety and efficacy of MCM candidates. Because adapted strains provoke a response from the host immune system, use of these strains can reveal MCM side effects or adverse reactions that are not seen in asymptomatic models, an important aspect of safety testing.

9.3.5.4.2 Vaccine Development Benefit 4: Developing Broad-Spectrum Vaccines

Chimeric bat-SARS CoV strains created using GoF approaches that adapt a virus to a new host are **uniquely capable** of providing reliable information about the broad-spectrum potential of CoV MCMs. Because most bat CoV strains cannot be cultured, the use of wild type viruses cannot provide information about whether CoV MCMs are capable of targeting a variety of SARS/MERS-like CoVs in addition to SARS and MERS. While expressing CoV Spike proteins in the context of other viruses (i.e., pseudotyped viruses and other chimeric virus systems) may be useful for screening MCM candidates targeting the Spike protein, all results must be confirmed using wild type strains (or CoV chimeric strains) due to significant differences in the behavior of chimeric viruses versus CoVs.

9.4 Introduction to GoF Research Involving Influenza Viruses

9.4.1 Overview of the Landscape of GoF Research Involving Influenza Viruses

Section 9.4 through Section 9.11 describe the benefits of GoF approaches involving influenza viruses, based on an analysis of the outcomes of GoF experiments published in the scientific literature. Our review of the influenza virus literature included the following virus strains:

- Human seasonal strains: currently circulating and historical influenza A H1N1 and H3N2 viruses and influenza B viruses,
- Human pandemic strains: the 1918 H1N1, 1957 H2N2, 1968 H3N2, and 2009 H1N1 viruses,

- Swine-origin strains: H3N2v and others, and
- Avian-origin strains: H5N1, H7N9, H9N2 and others.

We identified approaches involving influenza viruses that are reasonably anticipated to lead to the following phenotypic changes:

- Enhanced pathogen production as a result of changes in the replication cycle or growth,
- Enhanced morbidity and mortality in appropriate animal models,
- Altered host range,
- Enhanced transmission in mammals,
- Evasion of existing natural or induced immunity,
- Evasion of therapeutics, and
- Evasion of vaccines in development.

Through this document, the term "therapeutics" includes drugs that directly target viruses (e.g., influenza neuraminidase inhibitors), monoclonal antibody-based therapeutics, host immune modulators, and any other type of antiviral therapeutic. Influenza research that is reasonably anticipated to lead to evasion of diagnostics was not identified.

Descriptions of individual experimental approaches are provided within individual GoF phenotype sections. Of note, passaging of influenza viruses and coronaviruses in cells is essential for any experimental work involving live viruses, both to prepare virus stocks for experimental use and to conduct infection experiments. This applies to alt-GoF approaches, such as characterization of wild type viruses, as well as to GoF approaches. Because of the high mutation rates of RNA viruses, including influenza viruses and coronaviruses, such passaging inevitably selects for higher-yield viruses.[524] However, within the "enhanced virus production" phenotypic category, this analysis is restricted to those approaches that deliberately seek to enhance virus production through serial passaging, targeted genetic modification, or other approaches.

9.4.2 Use of Attenuated Strains of Influenza Viruses

Throughout the field of influenza research, the use of reassortant strains comprised of gene segments from a wild type strain and an attenuated, high-yield lab-adapted strain (e.g., A/Puerto Rico 8—PR8) is common. As described in Section 4.4.2.1, these strains are comprised of the HA and NA genes from a wild type strain and the remaining six genes from PR8 ("6:2R strains") and can be generated through reverse genetics or classical co-infection methods. 6:2R strains can be considered GoF strains by two criteria: (1) 6:2R strains exhibit enhanced virus production relative to the parental wild type strain (albeit reduced virus production relative to the parental lab-adapted strain), and (2) 6:2R strains exhibit enhanced pathogenicity relative to the parental lab-adapted strain (albeit reduced pathogenicity relative to the parental wild type strain). These strains are used for two purposes. In the context of vaccine production and basic science research that aims to elucidate mechanisms regulating the growth of vaccine viruses (Section 4.4.2.1), 6:2R strains are utilized due to their enhanced growth phenotype, which is desirable for efficient vaccine production. Therefore, when considering enhanced viral growth, the generation and use of 6:2R strains is considered to be a GoF approach. In contrast, in the context of research involving the study of other GoF phenotypes associated with the HA and NA proteins, 6:2R strains are utilized due to their attenuated phenotype, as a risk mitigation strategy. (In this context, 7:1R strains, comprised of the

[524] Parvin JD *et al* (1986b) Measurement of the mutation rates of animal viruses: influenza A virus and poliovirus type 1. *Journal of virology* 59: 377-383

HA and/or NA genes from the wild type strain and the remaining six or seven genes from PR8, may also be used.) Specifically, researchers may perform GoF approaches, such as serial passaging of viruses in the presence of cognate antibodies to select for antibody escape mutants, using 6:2R strains in lieu of wild type viruses. Thus, in these studies, 6:2R strains are subjected to an additional GoF approach. These studies include:

- Antigenic escape studies, which may lead to the generation of viruses that evade existing natural or induced adaptive immunity,
- Emergence of antiviral resistance studies, which may lead to the generation of viruses that evade therapeutics,
- Some approaches that may lead to the generation of viruses with enhanced pathogenicity, and
- Some approaches that may lead to the generation of viruses with altered host range in mammals and/or enhanced transmissibility in mammals.

In each of these sections, the use of 6:2R strains in place of wild type strains is considered to be an alternative approach for several reasons: (1) 6:2R strains are utilized due to their *attenuated* phenotype relative to parental, wild type strains, (2) the use of attenuated reassortant strains has been described as an alternative approach in the GoF debate, and (3) for a given GoF approach, the utility and limitations associated with the use of attenuated reassortant strains are different from those associated with the use of wild type strains and must be evaluated separately.

Several other risk mitigation strategies that involve the use of attenuated or replication-incompetent strains may be used for select GoF approaches in lieu of wild type strains. For those GoF approaches that may enhance pathogenicity, alter host range, or enhance transmissibility and that focus on the function of influenza proteins other than the HA and NA, another type of risk mediation reassortant may be used. Specifically, these reassortants comprise the HA and/or NA genes from a human seasonal flu strain, to which the population has pre-existing immunity, and up to the remaining six or seven genes from animal influenza strains or the 1918 H1N1 pandemic strain. As for attenuated reassortants with PR8, the use of these strains is considered to be an alternative approach because the purpose for their use is their attenuated phenotype and because their utility and limitations for a given GoF approach are different from those of the wild type strains.

For select GoF studies involving highly pathogenic avian influenza (HPAI) viruses, the multi-basic cleavage site (MBCS) of the viral surface glycoprotein HA, a major determinant of virulence, can be removed through deletion or mutation to mitigate risk. The MBCS is thought to mediate systemic replication and enhanced virulence in part by defining sensitivity to tissue specific proteases that are required for activation of the HA protein during infection. As a result, HPAIΔMBCS strains do not efficiently infect animal models and so cannot be used for *in vivo* studies; these attenuated strains can be used for select *in vitro* studies when cell culture media is supplemented with the appropriate proteases.

Replication-incompetent viruses can be used for the *in vitro* study of phenotypes underlying pathogenicity. In these model systems, viral replication and immune evasion pathways, both of which contribute to pathogenicity *in vivo*, can be assessed in cell culture lines that are engineered to stably express an essential viral protein that is missing from the "replication-incompetent" virus strains used for infection. For example, the replacement of the PB2 gene with a GFP-expression construct that has the necessary flanking, non-coding, and packaging sequences from the viral genome can only replicate in cell

lines that stably express exogenous PB2.[525] The result is a virus that is biologically constrained to replication in that cell line. Several replication incompetent model systems have been developed for the study of seasonal, pandemic, and animal influenza virus gene segments.

A final risk mitigation strategy that also modulates the replicative capacity of influenza viruses involves engineering binding sites for endogenous microRNAs (miRNAs) into the influenza virus genome. In cells that are expressing sufficient levels of the miRNA, miRNA binding to the viral RNA restricts viral replication. Incorporating target sites for miRNAs that are expressed in humans but not in an animal model of interest (e.g., ferrets) leads to the generation of a virus that is replication-competent in experimental animals but not humans, thus achieving "molecular biocontainment" of the virus. Langlois et al. pioneered this novel attenuation strategy in late 2013.[526] The authors incorporated target sites for miR-192, which is expressed in humans and mice but not ferrets, into the HA genome segment of two different strains: an attenuated lab reassortant strain and a seasonal H3N2 strain. The engineered strains displayed normal replication in ferrets but markedly reduced replication in mice and human cells, thereby providing proof of concept of this molecular biocontainment strategy. Importantly, incorporating miR-192 binding sites into the H3N2 strain did not prevent contact or airborne transmission of the virus in ferrets, demonstrating that the engineered virus behaves similarly to the wild type virus with respect to transmission dynamics. Though considered a promising risk mitigation approach by the influenza research community, other properties of the engineered viruses have not yet been extensively characterized, and the method has not been validated in other strains or using other miRNA target sites.

9.4.3 Organization of the Assessment of the Benefits of GoF Research Involving Influenza Viruses

The following chapters (9.5 through 9.11) summarize the results of the assessment of the benefits of GoF research involving influenza viruses. A more detailed analysis to further support the findings described in these chapters is presented in Appendix IV Section 15.2 through Section 15.8. As the relative ability of a given GoF (or alt-GoF) approach to address a particular scientific knowledge or public health gap often hinges on nuanced differences between the benefits and limitations of different approaches, readers who seek an in-depth understanding of the benefits of GoF research are directed to Appendix IV Section 15.

9.5 Influenza viruses: Benefits of GoF Research that Enhances Virus Production

9.5.1 Summary

This section describes the benefits of GoF research that is reasonably anticipated to lead to enhanced production of influenza viruses as the result of changes in the replication cycle or growth. Such GoF studies were found to generate scientific knowledge, have direct applications in vaccine development, and are likely to have economic benefits. Alt-GoF approaches that may generate similar benefits were also identified and analyzed. At present, GoF studies resulting in enhanced influenza production have unique and direct benefits, particularly to vaccine development and production. Chapter 9.5 provides an overview of these benefits, including basic background and Supporting Information; a fully referenced and more thorough discussion of these benefits can be found in Appendix IV Section 15.2.

---

[525] Ozawa M *et al* (2011) Replication-incompetent influenza A viruses that stably express a foreign gene. *The Journal of general virology* 92: 2879-2888

[526] Langlois RA *et al* (2013) MicroRNA-based strategy to mitigate the risk of gain-of-function influenza studies. *Nat Biotechnol* 31: 844-847

9.5.1.1 Benefits of GoF that Enhances Virus Production to Scientific Knowledge

- GoF approaches are:
  - Uniquely capable of discovering mutations that enhance the growth of vaccine viruses to greater-than-wildtype levels, which is desirable for vaccine production and provides a foundation for understanding the mechanistic basis of high growth of vaccine viruses.
  - Uniquely capable of demonstrating that particular markers are necessary and sufficient to enhance the growth of vaccine viruses, and
  - Uniquely critical for generating information that can be translated to the vaccine production process.
- Alternative experimental approaches are:
  - Limited to the study of genetic markers and phenotypes underlying naturally high levels of growth, and
  - Limited to confirming that mutations are necessary for high growth but cannot be used to demonstrate that mutations enhance growth, and thus cannot provide information that can be applied to the vaccine production process.

9.5.1.2 Benefits of GoF that Enhances Virus Production to Vaccine Production

- GoF approaches are:
  - Uniquely critical for the *current* capability to produce sufficient and effective vaccines for seasonal and pandemic influenza,
  - Capable of improving the quality and availability of influenza vaccines in the *future* by:
    - Shortening production timelines for egg- and cell-based vaccines, which translates to faster vaccine availability during a pandemic and improved vaccine match for seasonal influenza vaccines by enabling strain selection closer to the start of flu season,
    - Enabling the production of well-matched vaccines for strains that mutate to alter their antigenicity during growth in eggs or cells, which is a unique benefit of GoF approaches.
  - Because there are likely to be no regulatory barriers for incorporating genetic markers identified through GoF research into vaccine strains, this benefit can be achieved in the immediate to near future.
- Alternative approaches are:
  - Incapable of replacing current vaccine production processes in the near-term,
  - Capable of improving the quality and availability of influenza vaccines in the *future* through several different mechanisms:
    - Incorporating adjuvants into existing vaccines would shorten production timelines by enabling the use of smaller quantities of antigen per vaccine dose. However, no adjuvanted seasonal vaccines are FDA-licensed, and the development and licensing procedures for new adjuvanted vaccines are lengthy and expensive,
    - New virus-free vaccine platforms that do not rely on GoF are capable of producing strain-specific vaccines on shorter timescales than existing egg- and cell-based production

systems. However, only one recombinant vaccine is licensed, and the development and licensing procedures for new vaccines are lengthy and expensive.

- Developing a universal or broad-spectrum flu vaccine would obviate the need for annual production of seasonal vaccines and for production of strain-specific vaccines in response to the emergence of a novel pandemic strain. However, the feasibility of producing a universal flu vaccine is unknown.
- Developing pre-pandemic vaccines would lead to faster vaccine availability during a pandemic. However, because resources for pre-pandemic vaccine development and stockpiling are limited, pre-pandemic vaccines function to bridge the gap between the emergence of a novel strain and the large-scale deployment of strain-specific vaccines.
- Improving strain selection capabilities will reduce the likelihood of vaccine mismatch due to incorrect prediction of which strains will be circulating six to nine months hence. The realization of this benefit, which complements efforts to shorten vaccine production timelines by addressing a different shortcoming in the existing vaccine production process, depends on scientific advancements.

9.5.1.3 Economic Benefits of GoF that Enhances Virus Production

- Increasing the yields of vaccine viruses, using information or products derived from GoF approaches that enhance virus production, is likely to lower the cost per vaccine dose by enabling the production of a greater number of vaccine doses using the same materials.

GoF approaches that enhance virus production do not benefit surveillance, informing policy decisions, or the development of therapeutics or diagnostics.

9.5.2 Overview of GoF Research Landscape: Enhanced Virus Production

9.5.2.1 Generation of Attenuated, High-Yield Candidate Vaccine Viruses Through Reassortment

Reassortment between a wild type strain and an attenuated, high-yield vaccine backbone strain generates a "Candidate Vaccine Virus" (CVV), which comprises the HA and NA genes from the wild type strain and the remaining six "internal genes" from the vaccine backbone strain. CVVs are attenuated and exhibit higher levels of growth relative to the parental, wild type virus. CVVs may be generated through classical reassortment methods, which involve co-infection of eggs or cells with the wild type strain and the vaccine backbone strain followed by antibody-based selection for viruses with the correct surface antigens, or through reverse genetics.[527] CVVs serve as the basis of vaccine strains that are used for the production of influenza vaccines in eggs or cells. Additionally, in the context of academic research, comparing the sequences of CVVs with varied growth properties enables the identification of mutations that are associated with high yield.

9.5.2.2 Serial Passaging of Viruses in Eggs or Cells

Serial passaging of viruses in eggs or cells selects for higher-yield viruses. This approach is currently used for the production of influenza vaccines in eggs or cells as well as for basic science research on the

[527] Use of classical reassortment methods to generate CVVs may lead to the generation of a 5:3 reassortment strain which includes the HA, NA, and one additional gene from the wild type strain and the remaining five genes from the vaccine backbone strain.

mechanisms underlying high growth of influenza viruses. For vaccine production, manufacturers serially passage CVVs in eggs or cells to generate high-yield vaccine seed strains that can be used for large-scale production of vaccines. In the context of scientific research, serial passaging of viruses in eggs or cells followed by sequencing of the emergent higher-yield viruses enables the identification of mutations that are sufficient to enhance the growth of viruses. Subsequently, mutant viruses are subjected to antigenic characterization using the hemagglutinin inhibition (HAI) assay or other assays to identify which mutations confer high growth without changing the antigenicity of the strain. For research purposes, this approach is most commonly carried out using vaccine backbone strains and CVVs but may also be carried out using wild type strains.

9.5.2.3 Forward Genetic Screen to Identify Mutations that Confer High Growth to Viruses

Forward genetic screens, which involve random mutagenesis of viruses followed by limited passaging to select for mutants with high growth properties, enable the identification of mutations that confer high growth to viruses. Forward genetic screens involving vaccine backbone strains and CVVs lead to the identification of mutations that are sufficient to enhance the yields of vaccine viruses. Subsequently, mutant viruses are subjected to antigenic characterization using the hemagglutinin inhibition (HAI) assay or other assays to determine which mutations confer high growth without altering the antigenicity of the strain.

9.5.2.4 Targeted Mutagenesis of Viruses to Introduce Mutations That are Associated with High Growth

Targeted mutagenesis of viruses to introduce mutations that are associated with high growth, followed by characterization of virus yields relative to the parental virus, demonstrates that a mutation or set of mutations is necessary and sufficient to confer high growth. Subsequently, antigenic characterization assays are performed to confirm that the mutations have not altered the antigenicity of the virus, and the mutant strain is subjected to several rounds of passaging in eggs or cells to ensure that it is genetically stable – that is, that it does not acquire additional mutations that alter its antigenicity upon further growth. This knowledge provides a foundation for follow-up studies investigating the mechanistic basis of the high-growth phenotype (e.g., the use of cell biological assays, biochemical assays, and other assays to explore how the mutation enhances growth). Notably, these mutations may have been discovered through a GoF approach, such as serial passaging or a forward genetic screen, or through an alt-GoF approach, such as comparative analysis of wild type sequences.

Finally, it should be noted that experimental approaches involving targeted genetic modification of the viral polymerase complex of avian viruses to render it more "human-like" (through site-directed mutagenesis or reassortment between human and avian viruses) is also likely to enhance virus replication. However, as the primary goal of those studies is to gain insight into the mechanisms underlying adaptation of avian viruses to mammals, those studies are discussed in the "enhanced transmission in mammals" section.

9.5.3 Identification of Potential Benefits and Limitations of GoF Approaches

In this section, the potential benefits of GoF research that enhances virus production in each benefit category listed in the NSABB Framework are discussed.

9.5.3.1 Scientific Knowledge Benefits

The mechanistic basis of high growth of vaccine viruses in eggs or cells is not well understood. Current strategies for producing vaccine viruses do not consistently produce high-yield strains, which are needed

for efficient vaccine production. In addition, further boosting the growth properties of all vaccine strains has potential to increase the efficiency of the existing vaccine production process. The genetic and phenotypic traits that promote the growth of vaccine strains are largely unknown.

GoF approaches that enhance virus production have the potential to address this scientific knowledge gap by providing insight into the genetic and mechanistic basis of the enhanced growth phenotype. Specifically, serial passaging of viruses in eggs/cells and forward genetic screens followed by selection of high-growth mutants enable the identification of mutations that are sufficient to confer higher-than-wildtype levels of growth to any virus strain, though results may not translate to other virus strains. Comparative analysis of the sequences of CVVs with varying growth properties can also lead to the identification of mutations that are associated with naturally high levels of growth and may be more likely to uncover determinants of high growth that are conserved across multiple strains. However, comparative sequence analysis is unlikely to uncover genetic markers associated with greater-than-wild type levels of growth because it is limited to analysis of existing isolates. Finally, targeted mutagenesis can be used to demonstrate that a particular mutation or set of mutations is necessary and sufficient to enhance the growth of a vaccine virus strain, across multiple strain contexts. Collectively, these approaches provides a foundation for follow-up structural, biochemical, and cell biological assays investigating the phenotypic consequences of the mutations to gain insight into the mechanisms underlying the enhanced growth phenotype.

9.5.3.2 Surveillance

All other GoF approaches are focused on identifying mutations that confer high growth to vaccine viruses (either candidate vaccine viruses or vaccine backbone strains). Because these viruses have no correlate in nature, this information does not inform the interpretation of genetic surveillance data from animals or humans.

9.5.3.3 Development and Production of Vaccines

9.5.3.3.1 Background – Shortcomings in Existing Influenza Vaccine Production Processes

GoF approaches that enhance virus production have the potential to benefit the development of influenza vaccines, which are strain-specific. Due to antigenic drift of circulating seasonal influenza viruses, the strain composition of influenza vaccines must be updated annually, and the CDC's Advisory Committee on Immunization Practices recommends annual influenza vaccination for all people ages six months and older.[528] Currently, over 99% of seasonal influenza vaccines used in the US are produced in eggs or cells, and the same systems and facilities would be used to produce pandemic vaccine in response to the emergence of a novel pandemic strain of influenza.[529,530] For production of both seasonal and pandemic influenza vaccines, the vaccine production cycle spans six to eight months.[531,532]

Though the influenza vaccine development and production systems are well-established, interviews with stakeholders in the influenza research and public health communities highlighted that the lengthy production timelines for existing egg- and cell-based vaccines critically limit the mitigating impact of

influenza vaccination on the morbidity and mortality associated with influenza outbreaks. Lengthy vaccine production timelines impact the quality and availability of seasonal and pandemic flu vaccines differently. In the context of seasonal flu epidemics, existing production timelines necessitate strain selection nine months in advance of the peak of the target flu season.[533] As a result, one or more vaccine strains are often imperfectly matched to circulating strains, which reduces the efficacy of the vaccine.[534] In the context of pandemics, vaccines are simply unavailable to protect the public until at least six months into the outbreak.[535,536]

9.5.3.3.2 Potential Benefits and Limitations of GoF Approaches to Current Influenza Vaccine Production

GoF approaches are core aspects of the current process for producing influenza vaccines. To be suitable for large-scale manufacturing of vaccine virus, a selected field isolate must be attenuated and its growth in eggs/cells must be enhanced. This enhancement is achieved through the use of two different GoF approaches: (1) a CVV is created through reassortment between the field isolate and an attenuated, high-yield vaccine backbone strain and (2) the CVV is serially passaged in eggs or cells to increase its yield. Collectively, these GoF approaches increase HA antigen yield by yield at least 12-fold relative to the cognate wildtype strain.[537] (It should be noted that manufacturers report production increases in terms of HA antigen yield rather than viral titer because the FDA requires that a certain quantity of HA antigen be present in each vaccine dose. Increases in viral titer correlate with increases in HA antigen yields.)[538,539] The use of high-growth reassortant viruses generated through GoF methods enables the production of over 170 million doses of seasonal influenza vaccine annually and would enable the production of a similar number of doses of pandemic vaccine six to eight months after the emergence of a novel pandemic strain.[540]

9.5.3.3.3 Potential Benefits and Limitations of GoF Approaches to Future Influenza Vaccine Production

The insights gleaned from GoF approaches that enhance virus production also have the potential to improve vaccine production practices in the future through two distinct mechanisms: (1) shortening vaccine production timelines, and (2) improving the match between the virus strains used as the basis of vaccine strains and the strains that are circulating during flu season (referred to as "vaccine match").

First, GoF approaches have the potential to shorten vaccine production timelines by increasing the yields of vaccine viruses, which govern the rate at which vaccines are produced and thus serves as a key determinant of the time needed for egg- and cell-based vaccine production. GoF approaches can increase CVV yields in two ways: (1) through the direct use of higher-yield CVVs and (2) through the incorporation of genetic markers that confer high growth into existing CVVs using targeted mutagenesis. Shortening vaccine production timelines improves seasonal and pandemic influenza vaccines through different mechanisms. In the context of pandemics, faster vaccine production translates to vaccine availability earlier during the pandemic. In the context of seasonal flu epidemics, the ability to produce

vaccines in a shorter period of time enables strain selection closer to the start of flu season, increasing the likelihood that the vaccine strains will match the circulating strains during peak flu season. Ultimately, increasing the availability of vaccines during a pandemic and increasing the efficacy of vaccines during seasonal flu epidemics will reduce human morbidity and save lives.[541]

One key constraint on the benefits afforded by improvements to CVV yields is the limited production capacity of eggs and cells. Current *egg*-based vaccine production systems are at or near maximal levels of production, suggesting that the benefits of GoF research are largely limited to improving the growth of "poor" CVVs.[542] However, because many CVVs based on zoonotic viruses and seasonal H3N2 viruses grow poorly in eggs, simply improving their production would significantly benefit public health.[543,544] In contrast, the production capacities of *cell*-based systems have not yet plateaued, thus GoF research that improves CVV yields has the potential to benefit production of vaccines for all influenza sub-types using cell-based systems.[545] Importantly, because minor modifications to existing CVVs are unlikely to require FDA approval for use in vaccine production, these benefits can be realized in the immediate future.[546]

Second, the insights derived from GoF research can improve vaccine match for vaccines based on strains that tend to mutate upon growth in eggs or cells, which may lead to antigenic changes and poor vaccine match. In particular, H3N2 strains often acquire antigenicity-altering mutations upon growth in eggs, which is especially concerning given that H3N2 strains tend to cause more severe disease than H1N1 strains.[547,548,549,550] Mutations that enhance the growth of these strains without altering antigenicity, identified through GoF studies, can be incorporated into CVVs to enable the production of vaccines that match the antigenicity of selected strains.

9.5.3.4 Therapeutics and Diagnostics

Information about mutations that confer high growth to vaccine viruses or about mutations that rescue the growth of antiviral resistant strains is not relevant to the development of therapeutics.

The process of developing influenza diagnostics is well-established [551,552] GoF research that leads to the identification of genetic markers that confer GoF phenotypes, including enhanced virus production, does not inform diagnostic development.

9.5.3.5 Informing Policy Decisions

Similarly, information about mutations that confer high growth to vaccine viruses does not inform the analysis of genetic surveillance data, so this information does not benefit policy decisions about public health preparedness.

9.5.3.6 Economic Benefits

Increasing the yields of vaccine viruses, using information or products derived from GoF approaches that enhance virus production, is likely to lower the cost per vaccine dose by enabling the production of a greater number of vaccine doses using the same materials. However, the economic benefits of enhancements to vaccine virus yields to vaccine production were not explored in detail in this report.

9.5.4 Identification of the Potential Benefits and Limitations of Alt-GoF That Provide Similar Potential Benefits to the GoF Being Examined

In this section, an overview of alternative (alt-GoF) approaches that yield the same or similar benefits as the GoF approaches described above is provided. Two types of alt-GoF approaches are reviewed: (1) alternative experimental approaches that can provide the same or similar scientific information as GoF experimental approaches, and (2) alternative scientific and technical innovations that can yield the same public health benefits as GoF approaches but through different mechanisms.

9.5.4.1 Potential Benefits and Limitations of alt-GoF Approaches to Scientific Knowledge

Several alternative experimental approaches can provide insight into the genetic and mechanistic basis of high growth of vaccine viruses, which complement GoF approaches that lead to the identification of genetic traits that enhance virus growth. First, sequence comparison of wildtype strains with varied growth properties can lead to the identification of mutations that are associated with naturally high levels of growth. Of note, because of the importance of genetic context on multi-genic traits such as fitness, mutations that confer high growth to wildtype strains may not confer high growth to vaccine strains (i.e., reassortants that include the HA and NA from the field isolate and the remaining six genes from a vaccine backbone strain). Additionally, this approach depends on the existence of high-growth strains in nature and cannot identify mutations that confer exceptional yields.

Genetic screens to identify mutations that reduce growth (i.e., Loss of Function, or LoF) can lead to the discovery of mutations that are *necessary* for growth. A major limitation of this approach is that it may uncover mutations that reduce growth for "trivial," reasons (i.e., that modulate critical aspects of virus function that are necessary for viability but do not directly contribute to high growth). An additional drawback is that it is much less efficient than its GoF counterpart because mutants must be screened for reduced growth (versus selection for high growth through passaging). Finally, the utility of the information gleaned from LoF screens also depends on the existence of high-growth strains in nature.

---

551 New diagnostics for novel influenza viruses are typically real-time PCR assays which include two or three diagnostic targets. The influenza M gene is used as a marker for influenza A, the HA gene is used for sub-typing, and the NA gene may also be included. Developing of a new diagnostic assay simply requires designing new primers and probes for a virus of interest, which requires that the sequences of the M, HA, and NA genes are available.

552 (2015a) Interview with U.S. CDC (Centers for Disease Control) representative.

LoF approaches may also be used to confirm that a particular amino acid residue (discovered through GoF or alt-GoF approaches) is necessary for high growth. However, the marker may not be sufficient to enhance growth if introduced into a different strain, limiting the utility of this result for vaccine production.

9.5.4.2 Potential Benefits and Limitations of alt-GoF Approaches to Vaccine Production

9.5.4.2.1 Potential Benefits and Limitations of Alt-GoF Approaches to Current Influenza Vaccine Production

High-yield, attenuated vaccine viruses generated through GoF approaches are currently used for production of egg- and cell-based vaccines. The use of strains with wild type growth properties represents one alternative to the use of high-yield vaccine viruses. This could involve the direct use of wild type strains or the use of novel reassortant strains that are attenuated but exhibit wild type levels of virus production. Because most influenza strains grow poorly in eggs/cells, the concentration of virus antigen in eggs/cells infected with strains with wild type growth properties would be so low that existing manufacturing processes would likely fail to purify antigen that meets FDA standards, resulting in **no vaccine produced**. Alternatively, a wild type isolate with exceptional growth properties could be used to produce the same number of doses over a longer period of time or to produce a smaller number of doses over the same period of time. For example, use of a wild type isolate the grows four times as well as an average strain would either lengthen the vaccine production timeline to more than one year or would reduce the number of doses produced two- to three-fold. Additionally, because wild type viruses with exceptional yields *and* appropriate antigenic properties are unlikely to be available, this scenario would likely result in the use of a poorly matched strain, leading to the production of a less effective vaccine.

Additionally, neither alternative (i.e., use of wild type strains or use of novel reassortants with wild type growth properties) can be implemented immediately. Large-scale production using wild type isolates for the purpose of producing inactivated vaccines would pose significant risks to vaccine manufacturers prior to the inactivation step, presumably requiring the construction of new manufacturing facilities capable of virus production under higher biocontainment conditions. Of note, field isolates cannot be used as a basis for live vaccines due to their pathogenicity. The alternative, use of attenuated vaccine viruses with wild type growth properties, would necessitate the development, and perhaps subsequent FDA licensing, of novel vaccine backbone strains that attenuate but do not confer high growth to reassortant viruses.

As described above, production of virus-based vaccines in eggs/cells necessitates passaging of the antigenic strain of interest to produce enough stock virus to infect eggs/cells for large-scale manufacturing, which inevitably selects for higher-yield viruses due to the high mutation rate of influenza viruses.[553] If this passaging were considered to be a GoF approach, in addition to the approaches described above that deliberately enhance the yields of vaccine viruses, then completely avoiding manipulations that are reasonably expected to enhance virus production precludes production of egg- and cell-based influenza vaccines. In that case, virus-free vaccine platforms, such as recombinant or DNA-based vaccines, represent an alternative to egg- and cell-based flu vaccines.[554,555,556] However, only one recombinant flu vaccine is commercially available and is only approved for use in people 18 years of age and older. This vaccine represented just 50,000 of more than 140 million doses administered during the

2014 – 2015 flu season.[557,558] Although other recombinant vaccines are in late stages of development, given the long and expensive product development cycle for new influenza vaccines– spanning eight to 12 years and costing 300 million to one billion dollars including research, clinical development, and registration with the FDA– alternative, virus-free flu vaccine platforms are not a viable *replacement* for egg- and cell-based vaccines in the immediate future.[559]

9.5.4.2.2 Potential Benefits and Limitations of Alt-GoF Approaches to Future Influenza Vaccine Production

Several alternative scientific and technical innovations have the potential to benefit vaccine production in the future. Of note, some of these innovations can improve the production of both seasonal and pandemic influenza vaccines, whereas others can only improve production of seasonal or pandemic vaccines. These differences reflect the fact that seasonal flu vaccines are produced annually in advance of flu season, whereas pandemic vaccines are produced in response to the emergence of a novel pandemic strain.

An alternative approach for improving vaccine virus yields without enhancing the inherent growth properties of CVVs is through modulation of the host cells that are used to produce virus. Specifically, identification of host genes that suppress viral growth provides a basis for development of specialized knockout cell lines that permit higher virus yields.[560] This approach has potential to benefit the production of seasonal and pandemic flu vaccines but has been tested on a limited number of strains. No modified cell lines are currently FDA-approved for vaccine production, and only one cell-based vaccine that could potentially make use of this technology is licensed in the US.[561] Cell lines must undergo extensive testing in order to be FDA-approved for influenza vaccine production prior to their commercial use, which will delay realization of this benefit.[562,563] Finally, because this approach increases viral titer, it is not less risky than GoF approaches than enhance the growth properties of vaccine viruses.

An adjuvant is a substance that is added to a vaccine to boost the body's immune response to the vaccine, and including an adjuvant in a vaccine may enable the use of a smaller quantity of antigen to induce the same level of protection ("dose sparing"). [564] Thus, incorporating adjuvants into existing egg- and cell-based vaccines represents a different strategy for shortening production timelines, by enabling production of the same number of doses over a shorter period of time. Most licensed vaccines in the US are not adjuvanted – one seasonal vaccine containing adjuvants was recently approved for use in people aged 65

and older, and one licensed pandemic influenza vaccine contains adjuvants.[565,566,567,568] Nonetheless, use of adjuvants to improve the immunogenicity of seasonal influenza vaccines is an active area of research. The major barrier to realization of this benefit is that existing vaccines that are re-formulated with adjuvant are considered new drugs by the FDA and as such must undergo the standard licensure pathway for unadjuvanted vaccines, which will delay their widespread availability due to the time needed to generate the needed safety and efficacy data.[569,570,571] This approach has potential to benefit the production of seasonal and pandemic flu vaccines.

Developing new vaccine platforms with faster production timelines represents a third alternative approach for shortening the time needed for production of strain-specific vaccines. Recombinant vaccines, which are virus-free vaccines comprised of recombinant influenza proteins produced in insect cells or other protein expression systems such as plants, represent the most developed and promising approach.[572,573] Although only one recombinant vaccine is currently FDA-licensed, several other recombinant vaccines are in late stages of development, and experts in the influenza vaccine field expect the production and use of this type of vaccine to increase over the next several decades.[574,575] However, as mentioned above, the time needed for completion of clinical trials and licensing delays the ability of this technology to impact influenza vaccination systems in the US in the near term (i.e., within the next few years).[576] Virus-free vaccine platforms can be used for the production of seasonal and pandemic influenza vaccines.

A universal or broad-spectrum flu vaccine would obviate the need for yearly production of strain-specific vaccines as well as the need to produce a strain-specific vaccine in response to the emergence of a novel pandemic strain. Such a vaccine could be administered in advance of a pandemic, generating pre-existing immunity in the population, or could be stockpiled and immediately deployed following the start of a pandemic. However, universal or broader-spectrum vaccines are still in early stages of development and represent an extremely challenging prospect given the high mutability of influenza viruses.

Development of pre-pandemic vaccines against circulating zoonotic influenza strains with pandemic potential would also lead to faster vaccine availability during a pandemic caused by a closely related

strain. Developing pre-pandemic CVVs and carrying out clinical trials would shorten vaccine production timelines, and stockpiling bulk antigen would allow for near-immediate deployment of vaccine following emergence of a pandemic strain. In addition, manufacturers' experience with production of the vaccine would likely streamline subsequent large-scale production during the pandemic.[577] Although the pre-pandemic vaccine strain is unlikely to exactly match the strain that emerges to cause a pandemic, use of adjuvants and prime-boost regimens broaden the protection that can be achieved using a strain-specific vaccine, such that pre-pandemic vaccines are highly likely to provide some level of protection against infection with a similar strain.[578,579,580,581,582] The benefit of developing pre-pandemic vaccines is constrained by the fact that resources for the development and stockpiling of pre-pandemic vaccines are limited. Resource limitations necessitate targeted, risk-based investments in pre-pandemic vaccine development, which are informed by GoF approaches that enhance the transmissibility and virulence of influenza viruses, discussed in detail in Section 9.6.3.3.[583]

Shortening vaccine production timelines (through GoF or alt-GoF approaches) represents one strategy for improving the match between seasonal flu vaccines and circulating strains, by enabling the selection of vaccine strains closer to the start of flu season. However, as long as vaccine strains must be selected in advance of flu season, there remains the possibility of vaccine mismatch due to incorrect prediction of which strains will be dominant during the target flu season. Therefore, improving strain selection capabilities represents a completely different mechanism for improving the efficacy of seasonal influenza vaccines. As discussed in detail in Section 9.8.5.3.1, both GoF approaches that lead to evasion of existing natural or induced adaptive immunity and alt-GoF approaches have potential to improve strain selection capabilities.

9.5.5 Comparison and analysis of the Potential Benefits of GoF Approaches Versus Alt-GoF Approaches

In this section, the potential benefits of GoF research that enhances virus production *relative* to alt-GoF approaches are discussed, in each benefit category that GoF approaches can address

9.5.5.1 Benefits to Scientific Knowledge

GoF approaches are **uniquely capable** of discovering mutations that enhance the growth of vaccine viruses to greater-than-wildtype levels, which is important for the efficient production of egg- and cell-based influenza vaccines. In addition, GoF approaches are **uniquely capable** of demonstrating that particular markers are necessary and sufficient to enhance the growth of vaccine viruses, which is essential for translation of information about high-growth markers to the vaccine production process. Together, this information provides a foundation for follow-up studies investigating the mechanistic basis of high virus yields. Alternative approaches have significant limitations for the study of high virus yields,

relative to GoF approaches. Comparative sequence analysis of wildtype viruses is limited to the study of genetic markers and phenotypes underlying naturally high levels of growth, which provides a limited range of information relative to GoF approaches. LoF approaches are much less efficient than GoF approaches, and mutations that attenuate growth may not confer high growth if introduced into a new strain. Neither alternative approach is capable of generating information that can be applied to vaccine productions.

9.5.5.2 Benefits to Vaccine Production

9.5.5.2.1 Benefits to Current Production of Influenza Vaccines

GoF approaches to enhance the growth of attenuated vaccine strains are a **uniquely critical component** of the current ability to produce sufficient and effective vaccines for seasonal and pandemic influenza. The use of strains with field-like growth properties in lieu of high growth reassortants generated using GoF approaches would result in the production of no vaccines, the production of a lesser quantity of vaccines that poorly match circulating strains, or the production of vaccines that poorly match circulating strains over an extended time period. Furthermore, using field strains would require the construction of new manufacturing facilities capable of virus production under higher biocontainment conditions, and using attenuated strains with wildtype levels of growth would require the development and possible FDA licensure of new vaccine backbone strains that are attenuated but do not confer high growth to reassortant viruses, delaying the implementation of either alternative approach. Recombinant vaccines and other virus-free vaccine platforms represent a promising approach for future influenza vaccine production, but the one recombinant vaccine that is currently licensed represents less than 1% of seasonal influenza vaccines administered annually, and lengthy regulatory processes will delay the availability of additional virus-free vaccines in the future.

9.5.5.2.2 Benefits to Future Production of Pandemic Influenza Vaccines

Both GoF approaches to improve CVV yields and alternative approaches have potential to reduce the time lag between the emergence of a novel pandemic strain in human populations and the widespread availability of a vaccine, thus reducing human morbidity and mortality during an influenza pandemic. GoF approaches to improve the yields of vaccine viruses are **uniquely capable** of achieving this benefit in the immediate to near term because use of this information capitalizes on existing infrastructure and faces no regulatory barriers to translation. Adjuvanted vaccines and virus-free vaccines also have shorter production timelines than existing egg- and cell-based vaccines, but the widespread availability of both types of vaccines will be delayed due to time needed for vaccine development and the generation of safety and efficacy data that is required for FDA licensure of new flu vaccines. Universal flu vaccines are not a viable option for protection against pandemic influenza in the near future, and whether the development of a universal or broad-spectrum vaccine is possible is unknown. The development of pre-pandemic vaccines represents a promising strategy due to their ability to provide broad-spectrum protection when adjuvanted. However, because resources limit the scope of the USG's investment in pre-pandemic vaccines, these vaccines will serve to bridge the gap between the emergence of a novel strain and widespread availability of vaccines and must be complemented by innovations to shorten vaccine production timelines.

9.5.5.2.3 Benefits to Future Production of Seasonal Influenza Vaccines

Both GoF approaches and alt-GoF approaches have potential to improve the match between seasonal influenza vaccines and strains that are circulating during flu season, thus improving vaccine efficacy and decreasing human morbidity and mortality associated with seasonal flu epidemics. This benefit can be achieved through several different mechanisms. One strategy is to improve the production of strains that

mutate to alter their antigenicity upon growth in eggs or cells, which results in the production of vaccines that are poorly matched to the selected strains. GoF approaches are uniquely capable of generating high-yield, genetically stable CVVs that do not acquire antigenicity-altering mutations during passage in eggs or cells. A different strategy is to shorten the time needed to produce influenza vaccines, which enables strain selection closer to the start of flu season. GoF approaches to improve the yields of CVVs are uniquely capable of achieving this benefit in the immediate to near term relative to alternative approaches for shortening vaccine production timelines, for the reasons described above. Finally, a completely different mechanism for increasing the likelihood of vaccine match is to improve strain selection capabilities, which can be achieved through both GoF and alt-GoF approaches (see Section 9.8.5.3.1). Though promising, benefits in this area rely on scientific advancements and the expansion of influenza surveillance networks, thus both the extent and timescales of the benefits are uncertain. Notably, because this approach addresses different underlying gaps in existing vaccine development and production processes, research in this area has potential to complement the benefits that can be achieved by GoF research that shortens vaccine production timelines by increasing CVV yields.

9.6 Influenza Viruses: Benefits of GoF Research That Enhances Mammalian Adaptation and Transmissibility

9.6.1 Summary

This section describes the benefits of GoF research that is reasonably anticipated to enhance the infectivity and transmissibility of influenza viruses in representative animal models. Such GoF studies were found to generate scientific knowledge and inform surveillance of circulating animal influenza viruses, which has downstream impacts on decision-making about USG investments in pandemic preparedness initiatives, such as pre-pandemic vaccine development. Alt-GoF approaches that may generate similar benefits were also identified and analyzed. At present, GoF studies resulting in enhanced infectivity and transmissibility in mammals have unique benefits to scientific knowledge, surveillance, and pandemic preparedness, though full realization of GoF benefits to public health requires significant scientific advancements. Section 9.6 provides an overview of these benefits, including basic background and Supporting Information; a fully referenced and more thorough discussion of these benefits can be found in Section 15.3.

9.6.1.1 Benefits of GoF that Enhances Mammalian Adaptation and Transmissibility to Scientific Knowledge

- GoF approaches are:
  - Uniquely capable of proactively determining whether any animal influenza virus can evolve the capacity for airborne transmission in mammals.
  - Uniquely capable of providing in-depth information about the evolution of mammalian adaptation/transmissibility in any animal influenza strain, and of determining the order of acquisition of changes that are necessary and sufficient to enhance infectivity/transmissibility in mammals. However, laboratory results may not translate to adaptation of animal influenza viruses to humans in nature.
  - Uniquely capable of discovering novel genetic and phenotypic traits underlying mammalian adaptation and transmissibility in any virus strain, and of establishing a causal link between a particular trait and enhanced mammalian adaptation/transmissibility. However, results from cell culture or animal studies may not translate to human disease.

- Alt-GoF approaches are:
  - Limited to determining whether existing animal influenza viruses can efficiently transmit between mammals.
  - Uniquely capable of providing direct insight into the evolutionary mechanisms underlying adaptation of animal influenza viruses to humans, but cannot provide direct insight into the evolution of human transmissibility, as animal influenza viruses that efficiently transmit between humans do not exist in nature.
  - Uniquely capable of identifying novel genetic traits associated with adaptation of animal influenza viruses to humans, but cannot identify traits associated with human transmissibility, as animal influenza viruses that efficiently transmit between humans do not exist in nature.
  - Capable of identifying novel genetic traits in known phenotypes underlying mammalian adaptation and transmissibility using *in vitro*, virus free systems, but results may not be recapitulated in the context of the full virus.

9.6.1.2 Benefits of GoF that Enhances Mammalian Adaptation and Transmissibility to Surveillance

- GoF approaches:
  - Provide a foundation for the development of rapid assays for phenotypes underlying mammalian adaptation and transmissibility, which have potential to increase the quantity and timeliness of phenotypic information about animal flu viruses detected through surveillance. However, the success of this approach is subject to significant advancements in the state of knowledge about mechanisms underlying mammalian adaptation and transmissibility.
  - Are uniquely capable of strengthening the predictive value of molecular markers for mammalian adaptation and transmissibility, which can be used to infer phenotype from sequence. Use of molecular markers in lieu of or to corroborate phenotypic testing results could improve the quality, timeliness, and quantity of phenotypic information about animal flu viruses detected through surveillance. However, the success of this GoF approach is subject to significant advancements in the state of knowledge about the mechanistic basis of mammalian adaptation and transmissibility, and all sequence-based predictions must be experimentally validated.
  - Are critical for improving computational models for predicting phenotypes underlying mammalian adaptation and transmissibility based on sequence, which could improve the quantity and timeliness of phenotypic information about animal flu viruses detected through surveillance. However, the success of this approach is subject to significant advancements in the state of knowledge about the mechanistic basis of mammalian adaptation and transmissibility, and predictions must be experimentally validated.
- Alt-GoF approaches:
  - Have significant limitations for advancing the development of rapid assays for phenotypes underlying mammalian adaptation and transmissibility and for strengthening the predictive value of molecular markers for mammalian adaptation and transmissibility.
  - Are also critical for improving computational models for predicting phenotypes underlying mammalian adaptation and transmissibility based on sequence, but through the generation of different types of data that complement data generated through GoF approaches.

- Phenotypic assays for mammalian adaptation and transmissibility are uniquely capable of providing direct information about each complex phenotype under controlled conditions, but results may be delayed relative to the publication of viral sequences or, in the future, the generation of data about underlying phenotypes through rapid assays.

9.6.1.3 Benefits of GoF That Enhances Mammalian Adaptation and Transmissibility to Decision-Making in Public Health Policy

- GoF approaches:
  - Are uniquely capable of strengthening the predictive value of molecular markers for mammalian adaptation and transmissibility, which moderately influence pandemic risk assessments of circulating animal influenza viruses, relative to other types of data that are considered in the assessment. Pandemic risk assessments guide downstream decisions about investments in pre-pandemic vaccines, which will increase vaccine availability during a pandemic if a similar strain emerges to cause a pandemic.
  - Molecular marker data plays a relatively more important role when novel influenza viruses first emerge in human populations, when epidemiological data are scarce and virological data are not yet available. The ability to conduct a rapid risk assessment using molecular marker data can provide a three to four week head start on vaccine production.
  - Molecular marker data can guide selection of particular viruses to use as the basis of pre-pandemic vaccines, when multiple viruses have similar epidemiological and virologic characteristics.
- Alt-GoF approaches:
  - Epidemiological data are the most influential data in a pandemic risk assessment, but transmissibility can be difficult to assess in human populations, and epidemiological data may be scarce when novel viruses first emerge in human populations.
  - Virologic data strongly influences pandemic risk assessments, but the generation of virological data may be delayed relative to the publication of sequencing data when novel viruses emerge abroad due to shipping delays.
  - Other types of data, such as ecological data, also contribute to pandemic risk assessments but complement molecular marker data (GoF) by evaluating completely different aspects of pandemic potential.

9.6.2 Overview of GoF Research Landscape: Enhanced Infectivity and Transmissibility in Representative Animal Models

9.6.2.1 Serial Passaging of Viruses in Mammalian Cells or Animals

Serial passaging of viruses in mammalian cells in laboratory animals selects for viruses with enhanced growth in cells or enhanced infectivity to animals, respectively. This type of serial passaging experiment involves "forced" passaging, meaning that the experimenter directly transfers infected material, in the form of cell culture supernatant or homogenates of infected tissue, to the subsequent cell culture dish or animal. Forced serial passaging is carried out for two purposes: (1) to identify mutations that arise during adaptation of animal influenza viruses (i.e., avian and swine viruses) to mammals, which provides a

foundation for follow-up studies investigating the evolutionary mechanisms driving adaptation to mammalian hosts and the mechanistic basis of mammalian adaptation, and (2) to develop an mouse model for the study of a particular virus.

9.6.2.2 Serial Passaging of Viruses in Mammalian Cells or Animals with Selection for Transmission

Serial passaging of viruses in animals with selection for transmission leads to the generation of viruses with enhanced transmissibility in mammals. This type of serial passaging experiment can involve selection for contact transmission, during which the primary (directly inoculated) and secondary hosts are co-housed, or for airborne transmission, during which the primary and secondary hosts are separately housed in special isolator cages that prevent direct contact between animals but allow for air exchange between cages. These studies seek to identify mutations that are sufficient to enhance transmissibility, which provides a foundation for follow-up studies that investigate the mechanistic basis of transmissibility in mammals.

9.6.2.3 Forward Genetic Screen to Identify Genetic Traits That Enhance the Fitness/Transmissibility of Viruses in Mammals

Forward genetic screens involve random mutagenesis of genetic regions predicted to contribute to fitness/transmissibility or comprehensive reassortment of parental gene segments from two viruses, followed by characterization of the fitness or transmissibility of mutants in appropriate mammalian model systems to select for mutant viruses with enhanced fitness/transmissibility. Sequencing emergent viruses enables the identification of mutations or gene segments that enhance the fitness/transmissibility of viruses, which provides a foundation for follow-up studies that investigate the mechanistic basis of transmissibility in mammals.

9.6.2.4 Targeted Genetic Modification of Viruses to Introduce Traits That are Expected to Enhance Fitness/Transmissibility in Mammals

Targeted genetic modification of viruses, namely site-directed mutagenesis and/or reassortment, to introduce genetic traits that are expected to enhance the fitness/transmissibility of viruses followed by characterization of the fitness or transmissibility of mutants in appropriate mammalian model systems may lead to the generation of viruses with enhanced fitness/transmissibility in mammals. This approach is performed for two purposes: (1) to determine whether a previously characterized underlying genetic or phenotypic trait, such as a preference for binding to α2,6 sialic acid receptors, contributes to the complex phenotypes of mammalian adaptation or transmissibility and (2) to confirm that a particular mutation or gene segment is necessary and sufficient to enhance the fitness/transmissibility of viruses in appropriate model systems. Notably, genetic traits that are associated with mammalian adaptation/transmissibility may be discovered through GoF approaches or alt-GoF approaches. As above, this information provides a foundation for follow-up studies investigating the mechanistic basis of mammalian adaptation and transmissibility.

9.6.3 Identification of the Potential Benefits and Limitations of GoF Approaches

In this section, the potential benefits of GoF research that enhances mammalian adaptation and transmissibility in each benefit category listed in the NSABB Framework are discussed.

9.6.3.1 Benefits and Limitations of GoF Approaches to Scientific Knowledge

GoF approaches have potential to benefit several aspects of scientific knowledge about the ability of animal influenza viruses to adapt to efficiently infect and transmit between humans. In this section, the

ability of GoF approaches to address three key outstanding questions related to influenza virus adaptation and transmission in humans is evaluated:

- *Can* animal influenza viruses become transmissible between humans?
- *How* do animal influenza viruses adapt to and become transmissible between humans? What selective pressures drive adaptation and the evolution of efficient transmissibility, and what is the order of acquisition of new genetic/phenotypic traits that are needed for adaptation/transmissibility?
- *What* is the mechanistic basis of adaptation and transmission in humans? What viral factors are involved, and what phenotypic changes must occur in order for an animal influenza virus to adapt to efficiently infect, cause disease, and transmit in mammals?

Viral fitness and transmissibility are complex phenotypes that arise through the cumulative effects of multiple underlying phenotypes, such as specificity for a particular type of cell surface receptor and the ability to replicate within a particular temperature range. Because the property of transmissibility depends on phenotypes underlying both adaptation and transmission and because similar experimental approaches are used to study both complex phenotypes, GoF experiments that enhance adaptation and transmissibility are discussed together. Several phenotypes have been shown to be associated with mammalian adaptation and transmissibility. However, considerable gaps in knowledge remain about the molecular basis of each known phenotype and the role of each phenotype in adaptation/transmissibility. In addition, as-yet-undiscovered viral factors and phenotypic changes are likely to contribute to the acquisition of efficient transmissibility in mammals. Furthermore, the potential for animal influenza strains to evolve efficient transmissibility in humans is not understood.

9.6.3.1.1 Scientific Knowledge Gap 1: Can Animal Influenza Viruses Become Transmissible Between Humans?

Several GoF approaches can lead to the generation of transmissible viruses, including deliberate genetic modification of viruses and serial passaging of viruses in animals with selection for transmission. Collectively, these approaches definitively demonstrate that a virus can acquire the capacity to transmit between laboratory animals in an experimental setting. Notably, this approach can be applied to strains that have not yet caused infections in human populations as well as strains that have caused human infections but do not yet efficiently transmit in humans. The key limitations of this approach are that observations in animal models may not translate to humans and that the adaptive changes observed in the laboratory may not be possible in nature.

9.6.3.1.2 Scientific Knowledge Gap 2: How Do Animal Influenza Viruses Adapt to and Become Transmissible in Humans?

Serial passaging of animal influenza viruses in appropriate animal models to select for mammalian adaptation and transmission, a GoF approach, provides insight into the mechanisms underlying adaptation to mammals and the evolution of transmissibility. Sequencing of isolates at multiple stages of passaging enables determination of the order and rate of acquisition of adaptive traits, and follow-up studies elucidate how those genetic and phenotypic changes influence other viral phenotypes. Comparing the sequences and phenotypes of viral isolates from different tissues, at different time points during the course of infection, and between the primary (directly inoculated) and the secondary hosts can provide additional insight into the tissue-dependence of adaptation, the rate of intra- and inter-host adaptation, and the selection pressures and viral population dynamics during transmission, respectively. Notably, the

adaptive changes that occur in the lab environment under forced selection may not be relevant or possible during natural evolution, may not mimic adaptation and transmission in humans, and may selectively represent the evolutionary course possible for the limited number of viruses studied.

Serial passaging provides information about the genetic traits that are associated with the acquisition of enhanced fitness and transmissibility in mammals. However, to confirm which of these changes are *necessary* and *sufficient* to enhance fitness and transmissibility, targeted mutagenesis must be used to re-introduce mutations into parental strains followed by characterization of the infectivity/transmissibility of mutant strains. Targeted mutagenesis also enables determination of how the order of acquisition of genetic changes influences other viral phenotypes, such as replicative fitness, which has implications for the likelihood that these traits can arise in nature.

9.6.3.1.3 Scientific Knowledge Gap 3: What are the Genetic and Phenotypic Traits That Result in Adaptation and Transmission in Humans?

Several GoF approaches can be used to discover the genetic and phenotypic markers underlying mammalian adaptation and transmission of animal influenza viruses include:

- Targeted genetic modification to introduce novel genetic changes that are expected to contribute to adaptation and transmission in mammals by either site-directed mutagenesis or targeted reassortment (often between animal and human seasonal strains),
- Forward genetic screens involving random mutagenesis or comprehensive reassortment followed by selection for mammalian infectivity, transmissibility, or underlying phenotypes, and
- Serial passaging in appropriate animal models or mammalian cells to select for mammalian adaptive or transmissible traits.

Collectively, these approaches enable the identification of genetic changes that are sufficient to confer enhanced fitness in cell culture model systems or infectivity and transmissibility in animal models, which provides a foundation for follow-up biochemical, cell biological, and structural studies that elucidate associated phenotypic changes. Serial passaging has the potential to uncover *novel* genetic and phenotypic markers that contribute to adaptation/ transmissibility. In contrast, because forward genetic screens involving random mutagenesis typically focus on regions that are suspected or known to play a role in phenotypes underlying adaptation/transmissibility, this approach can discover novel *genetic* markers for adaptation/transmissibility only. The targeted genetic modification approach is limited to the investigation of genetic traits and underlying phenotypes that are suspected to contribute to adaptation/transmissibility (e.g., determining whether altering sialic acid receptor binding specificity contributes to transmissibility). Targeted genetic modification is also used to confirm that particular mutations or gene segments are *necessary* and *sufficient* to enhance infectivity or transmissibility in mammals. The use of *in vitro* model systems is limited to the investigation of phenotypes underlying adaptation and transmissibility, such as replicative fitness and sialic acid receptor specificity. Moreover, the results derived from these studies may not be recapitulated in the complex environmental pressures encountered in a host. The relevance of both *in vitro* and *in vivo* approaches depends on whether mechanisms underlying adaptation to cell culture and animal models are representative of those in humans, and results gleaned from the study of one or a few strains may not be recapitulated in different genetic contexts.

9.6.3.2 Benefits and Limitations of GoF Approaches to Surveillance

This section collectively evaluates the benefits of GoF research that enhances mammalian adaptation, transmissibility, or virulence to surveillance, as the strategies for monitoring the evolution of all three properties in circulating animal influenza viruses and the potential benefits of GoF approaches are similar.

GoF approaches that lead to the identification of genetic and phenotypic traits underlying mammalian adaptation, transmissibility between mammals, and virulence have the potential to inform the interpretation of wildlife, agricultural animal, and public health surveillance data. Specifically, GoF data has potential to improve three practices for evaluating the infectivity, transmissibility, and virulence of surveillance isolates: (1) inspecting sequences for the presence of molecular markers for mammalian adaptation, transmissibility, and virulence, (2) developing rapid assays for phenotypes underlying mammalian adaptation, transmissibility, and virulence, and (3) developing computational models for predicting underlying phenotypes. Information about the infectivity, transmissibility, and virulence of circulating animal influenza viruses is one aspect of evaluating their risk to human populations, which informs downstream decision-making related to public health preparedness for novel influenza outbreaks. The contribution of GoF data to pandemic risk assessments is discussed in detail in Section 9.6.3.3.2, below.

9.6.3.2.1 Introduction to Influenza Virus Surveillance: Current Practices and Limitations

Influenza surveillance is conducted in human and animal populations, including agricultural animals, companion animals, and wildlife. Collectively, the goal of this surveillance is to monitor the evolution of circulating animal influenza viruses, in order to detect the emergence viruses that pose a risk of emerging in human populations to cause a pandemic. Resources can then be dedicated to mitigating the risk factors associated with virus emergence, for example through community-level interventions at the animal-human interface, and to preparing for a potential emergence event, for example through the development of pre-pandemic vaccines.[584] Analysis of the phenotypic properties of individual surveillance isolates is a key aspect of assessing their pandemic potential. This section focuses on GoF benefits to that surveillance effort.

The WHO Global Influenza Surveillance and Response System (GISRS) serves as a central repository for data about animal influenza infections in humans. GISRS is a two-tiered surveillance and public health laboratory system.[585,586] A global network of National Influenza Centres (NICs) collect clinical specimens in their countries, perform preliminary analyses such as viral isolation and sub-typing, and forward specimens with suspect animal influenza infections to one of six WHO Collaborating Centres (WHOCCs) for further characterization.[587]

Multiple virus properties contribute to the likelihood that the virus will adapt to efficiently transmit in human populations and the potential consequences of that event, including whether the virus is adapted (or poised to adapt) to efficiently infect and transmit between humans and viral virulence. These properties can be directly measured in the laboratory or can be inferred from the genetic sequence based on the presence of molecular markers that have been linked to those phenotypes through previous research. In practice, due to caveats associated with both strategies, both are utilized. Two other approaches are in development but are not yet used in public health practice. The first involves the use of

---

585 (2015p) Interview with Centers for Disease Control and Prevention representative.
586 WHO. Global Influenza Surveillance and Response System (GISRS). http://www.who.int/influenza/gisrs_laboratory/en/. Last Update Accessed December 7, 2015.
587 WHOCCs include the U.S. Centers for Disease Control in Atlanta, GA and St. Jude Children's Research Hospital in Memphis, TN.

rapid assays to measure phenotypes underlying mammalian adaptation, transmissibility, and virulence (i.e., versus evaluating the complex phenotype through animal experiments). The second involves computational modeling to predict phenotype from genotype, which incorporates experimental data about mutations that give rise to phenotypic changes, structural data, and other types of data. This section evaluates how GoF approaches can benefit surveillance by improving strategies for evaluating mammalian adaptation, transmissibility, and virulence through the use of molecular markers, the use of rapid phenotypic assays, and the use of computational models. First, the utility and limitations of traditional methods for laboratory evaluation of the infectivity, transmissibility, and virulence of viruses are evaluated. This information motivates the need for development of additional approaches that can provide information about these virus properties.

The pathogenicity and transmissibility of animal influenza viruses in mammals is typically evaluated in ferrets.[588] The strength of these assays is that they directly measure the complex properties of mammalian adaptation, transmissibility, and virulence. However, multiple shortcomings are associated with reliance on these assays. First, these assays are unable to assess when viruses have acquired underlying properties that are necessary but not sufficient to enhance infectivity, transmissibility, or virulence. Such knowledge about partial adaptation is of interest for pandemic risk assessments. Second, these assays require the use of surveillance isolates, which limits the number of viruses that can be subjected to phenotypic characterization.[589] Third, transmission and virulence testing in animals requires technical expertise and must be conducted under BSL-3 conditions, limiting the conduct of these assays to the six WHOCCs.[590] This restriction is problematic when logistical, political, and regulatory factors delay the shipment of virus samples from NICs and other field diagnostic laboratories to WHOCCs, thereby delaying the generation of phenotypic data.[591,592]

For the reasons listed above, the CDC has incorporated the use of molecular markers for phenotypes of concern into the pandemic risk assessment process to complement virologic data. Because the phenotypes of mammalian adaptation, transmissibility, and virulence are complex, arising from the interplay between multiple underlying phenotypes, this strategy involves inspecting sequences for markers that are casually linked to underlying phenotypes (e.g., altered sialic acid receptor binding specificity). Because a constellation of amino acid changes is needed for an animal virus to evolve to efficiently infect, transmit, and cause disease in people, molecular markers are considered collectively to determine the overall risk associated with a virus. Importantly, this process assumes that the complex phenotypes of mammalian adaptation, transmissibility, and virulence can accrue in a step-wise fashion, such that "partially adapted" viruses can persist in nature.

Influenza research experts agree that the state of this science does *not* enable accurate and reliable predictions of phenotype from genotype for complex phenotypes such as mammalian adaptation, transmissibility, and virulence. Multiple sources of scientific uncertainty limit current capabilities, which can be broadly grouped into two categories: (1) uncertainties related to the phenotypes underlying adaptation, transmissibility, and virulence and (2) uncertainties related to the genetic traits that alter underlying phenotypes.

591 Ibid.
592 WHO (2011) Pandemic influenza preparedness framework for the sharing of influenza viruses and access to vaccines and other benefits.

Uncertainties related to phenotypes underlying mammalian adaptation, transmissibility, and virulence:

1. Weak linkage between underlying phenotypes and adaptation/transmissibility/virulence – that is, uncertainty in whether particular underlying phenotypes, such as altered sialic acid receptor binding specificity, are necessary for complex phenotypes, such as mammalian adaptation across many different virus strains.

2. Lack of knowledge about how underlying phenotypes interact to alter adaptation, transmissibility, and virulence (i.e., how to integrate the presence of multiple markers to appropriately determine overall risk).

3. Lack of knowledge about whether complex phenotypes can slowly accrue (i.e., whether partially adapted viruses can persist in nature) or whether the acquisition of efficient infectivity, transmissibility, and enhanced virulence in mammals is an "all-or-none" phenomenon.

Uncertainties related to the genetic traits that alter underlying phenotypes

1. Inability to predict whether a particular amino acid substitution will have similar phenotypic consequences in new genetic contexts.

2. Lack of knowledge about whether different amino acid substitutions at a particular amino acid position will have similar phenotypic consequences as known mutations.

3. Lack of knowledge about the mutational landscape that permits evolution of a complex phenotype – e.g., how many different sets of mutations enable the acquisition of airborne transmissibility? This knowledge gap influences whether the absence of a known marker is meaningful; if the mutational landscape is poorly understood, the "negative" strain could contain as-yet-undiscovered markers.

Collectively, these sources of uncertainty significantly compromise the predictive value of molecular markers for mammalian adaptation, transmissibility, and virulence.

Given the shortcomings associated with phenotypic assays and molecular marker data, the use of computational methods for sequence-based predictions of phenotypes underlying mammalian adaptation, transmissibility, and virulence has also been proposed. Although a variety of computational methods have shown promise for predicting phenotype from genotype, for those "known" phenotypes associated with adaptation/transmissibility, the accuracy of their predictions remains largely unknown.[593,594]

GoF approaches have potential to address shortcomings associated with the use of virological data, molecular markers, and computational methods to evaluate the infectivity, transmissibility, and virulence of animal influenza viruses in mammals, representing three different strategies for improving upon the status quo. The value of each strategy and the utility and limitations of GoF approaches for improving each strategy are discussed below.

9.6.3.2.2 Analysis of GoF Approaches That Support the Development of Rapid Phenotypic Assays

Strengths and weaknesses of using rapid phenotypic assays to inform pandemic risk assessments

Rapid assays to measure phenotypes underlying mammalian adaptation, transmissibility, and virulence could be performed in lieu of traditional evaluation of these complex phenotypes using ferrets. The development of rapid phenotypic assays holds promise for improving analysis of surveillance data for several reasons. First, the use of assays that are higher throughput than ferret testing will enable the phenotypic characterization of a larger number of viruses. Second, rapid phenotypic assays that require less technical expertise than ferret experiments are better suited for NICs, which would shorten the time lag between the initial detection and phenotypic characterization of a given virus. Thus, taken together, the development of rapid phenotypic assays has the potential to expand the quantity and the timeliness of phenotypic characterization data available for pandemic risk assessments. However, these assays will need to be carried out under BSL-3 conditions, which will limit the number of diagnostic laboratories that will be able to conduct the assays. (The majority of NICs do not have BSL-3 capabilities, though the number of NICs with BSL-3 capabilities or with access to BSL-3 labs has increased since 2005.)

In order for rapid phenotypic assays to be useful as proxies for mammalian adaptation, transmissibility, and virulence, the measured phenotype must be strongly linked to adaptation/transmissibility/virulence across many strain contexts. Additionally, interpretation of the results requires knowledge about how individual phenotypes contribute to overall pandemic risk, which relies on an understanding of how underlying phenotypes synergize to shape complex phenotypes. Gaps in scientific knowledge related to these two questions constrain the development and use of rapid phenotypic assays, as described above. As discussed in detail in Section 9.6.3.1.3, GoF approaches can provide insight into these scientific questions. The relevant findings are summarized below.

Summary – benefits of GoF approaches

GoF approaches represent the most efficient and effective approach for identifying novel *phenotypic* traits underlying mammalian adaptation, transmissibility, and virulence. Furthermore, targeted genetic modification of viruses to introduce genetic traits that alter underlying phenotypes is uniquely capable of demonstrating that a particular phenotype is causally linked to enhanced infectivity/transmissibility/virulence in mammals across multiple virus contexts. Additionally, the ability to alter phenotypes individually and in combination (i.e., through incorporation of varying sets of mutations) provides insight into how multiple underlying phenotypes interact to enhance infectivity, transmissibility, or virulence in mammals. This approach can also determine how an "intermediate" level of adaptation/transmissibility/virulence, i.e., acquisition of some but not all phenotypic traits that are required for viruses to efficiently infect, cause disease, and transmit in mammals, affects viral fitness, which may provide insight into whether such partially adapted strains can persist in nature. However, the major caveat associated with GoF approaches is that results gleaned from laboratory studies involving animal models may not translate to human disease in nature.

9.6.3.2.3 Analysis of GoF Approaches That Support the Use of Molecular Markers to Evaluate the Risk Posed by Circulating Animal Influenza Viruses

Strengths and weaknesses of using molecular marker data to inform pandemic risk assessments

The use of molecular marker data to evaluate the pandemic potential of animal influenza viruses has potential to improve the quantity and timeliness of phenotypic information about circulating animal influenza viruses. An increasing number of NICs and other diagnostic laboratories in developing countries have sequencing capabilities, and stakeholders involved in animal influenza surveillance stated

that viral genetic sequence data is currently the fastest and more reliable data generated by diagnostic labs in areas where viruses of concern are circulating.[595] Given the time needed for sample shipment to WHOCCs and ferret testing, the ability to assess the phenotypic properties of viruses based on sequence data can provide information before traditional phenotypic assays. Currently, most genetic surveillance data is generated by sequencing of viruses at WHOCCs.[596] Therefore, full realization of the benefits that can be derived from the use of molecular marker data will require an expansion of sequencing capabilities at diagnostic laboratories that comprise the "base" of the influenza surveillance system.

As described above, the current utility of molecular markers to the interpretation of genetic surveillance data is constrained by multiple sources of scientific uncertainty. Additionally, as knowledge about the phenotypes underlying mammalian adaptation, transmissibility, and virulence is incomplete, the discovery of additional molecular markers associated with novel underlying phenotypes would broaden the utility of this approach. As discussed in detail in Section 9.6.3.1.3, GoF approaches can provide insight into these scientific questions. The relevant findings are summarized below.

Summary – benefits of GoF approaches

GoF approaches represent the most efficient and effective approach for identifying novel genetic and phenotypic traits underlying mammalian adaptation, transmissibility, and virulence. Furthermore, targeted genetic modification of viruses to introduce genetic traits associated with mammalian adaptation/transmissibility/virulence is uniquely capable of establishing a causal link between a particular genetic or phenotypic trait and mammalian adaptation, transmissibility, or enhanced virulence across multiple strain contexts. In addition, GoF approaches, namely forward genetic screens, are uniquely capable of systematically exploring alternative mutational pathways for altering an underlying phenotype (e.g., changing sialic acid receptor binding specificity) in the context of whole virus. Finally, GoF approaches are also uniquely capable of providing definitive information about how multiple phenotypes synergize to promote mammalian adaptation, efficient transmissibility, and virulence. The major caveat associated with GoF approaches is that results gleaned from laboratory studies involving animal models may not translate to human disease in nature.

9.6.3.2.4 Analysis of GoF Approaches That Improve Predictive Models

Strengths and weaknesses of using computational models to inform pandemic risk assessments

As the use of computational models to predict phenotypes underlying mammalian adaptation, transmissibility, and virulence capitalizes on (and depends on) the availability of sequence data, the strengths and limitations of this approach are similar to those described above for the use of molecular marker data.

Existing computational models cannot reliably predict phenotypes underlying mammalian adaptation, transmissibility, and virulence based on sequence information. Additional experimental data is needed to appropriately parameterize models, and experiments must be conducted to validate the phenotypic predictions of models. GoF approaches can generate data that improves the accuracy of existing models.

Summary - benefits of GoF approaches

A variety of experimental data are needed to improve the accuracy of existing models, including data about mutations that do and do not give rise to phenotypic changes of interest. This data is critical for

[595] (2015e) Interviews with influenza researchers and government representatives involved in pandemic risk assessments.
[596] Ibid.

building models that can account for the context dependence of genetic changes in influenza biology. GoF approaches (targeted mutagenesis and forward genetic screens) are uniquely capable of generating these data in the context of the full virus, although *in vitro*, virus free approaches can also be used. Finally, model predictions must be validated experimentally, and results feedback to improve model accuracy. GoF approaches are uniquely capable of validation model predictions in the context of the full virus.

9.6.3.3 Benefits and Limitations of GoF Approaches to Inform Policy Decisions

GoF approaches that lead to the identification of molecular markers for mammalian adaptation and transmissibility between mammals contribute to assessments of the pandemic risk posed by circulating animal influenza viruses, which are based on genetic surveillance data and several other types of data (e.g., epidemiologic data, phenotypic data, etc.). These assessments inform policy decisions related to public health preparedness for novel influenza outbreaks, including whether to develop pre-pandemic vaccines. Additionally, the demonstration that avian influenza viruses can evolve the capacity for more efficient transmission in mammals may, in and of itself, stimulate interest and investment in pandemic preparedness initiatives. This section evaluates the potential benefits of GoF approaches in both areas.

9.6.3.3.1 Benefits of "Proof of Principle" GoF Research That Demonstrates the Capacity of a Virus to Evolve More Efficient Transmissibility in Representative Animal Models

Researchers have suggested that the "proof of principle" demonstration that an animal influenza virus can evolve the capacity for airborne transmission in a laboratory setting, as a blunt indicator of the pandemic potential of the virus, could inform government interest and investment in pandemic preparedness initiatives. However, pandemic preparedness activities at the US CDC and ASPR, including BARDA, did not change in the wake of the laboratory demonstrations that H5N1 and H9N2 could evolve the ability to transmit via the airborne route between ferrets in 2012 and 2009, respectively, suggesting that this is not a real benefit.[597,598,599] USG representatives involved in pandemic preparedness indicated that the response to the demonstration that an animal virus that has not yet caused human infections can evolve the capacity for airborne transmission would also be minimal, due to the lack of certainty about whether laboratory results translate to humans in nature.[600] If the virus were known or suspected to be circulating in animal populations in the US, enhanced surveillance might be undertaken to better understand the prevalence and geographic distribution of the virus in nature. However, the result would be highly unlikely to trigger investments in pre-pandemic vaccine development.

9.6.3.3.2 Benefits of GoF Research That Informs Pandemic Risk Assessments

The second mechanism through which GoF approaches can benefit pandemic preparedness planning is through pandemic risk assessments, downstream of GoF benefits to surveillance. As discussed in Section 9.6.3.2, GoF approaches have potential to benefit virological surveillance (i.e., by supporting the development of rapid phenotypic assays) as well as genetic surveillance (i.e., by strengthening the predictive value of molecular markers for phenotypic properties of concern and by improving computational models for predicting phenotype from genotype). The use of molecular markers for phenotypic properties of concern is currently incorporated into the risk assessment process, as described in detail below. As neither rapid assays nor robust computational models for relevant phenotypes exist, how results from notional future assays/models would be considered in risk assessments is uncertain.

Thus, the potential benefits of rapid phenotypic assays or computational models to pandemic risk assessments is not formally evaluated in this section, but a discussion of how results from either could contribute to the risk assessment process is provided at the end of the section.

This section analyzes the value of using molecular marker data relative to other types of data that are considered in the pandemic risk assessment process, which provides an "upper bound" to the public health benefits that can be achieved through GoF improvements to surveillance. First, to provide context for this analysis, current strategies for pandemic risk assessments are reviewed, and shortcomings in existing processes are highlighted.

Background – pandemic risk assessment and strategies for decision-making about investments in pandemic preparedness

The US government undertakes influenza pandemic preparedness activities that aim to bolster US capabilities for rapid detection of novel influenza events and to limit the spread of disease, death, and potential societal impacts if/when the next influenza pandemic occurs.[601] In particular, the development of pre-pandemic vaccines is a key aspect of pandemic preparedness because influenza vaccination is the primary public health strategy during outbreaks.[602] As resources for pandemic preparedness efforts are limited, a major challenge is determining how resources for the development of pre-pandemic vaccines and other preparedness activities should be allocated. To that end, the CDC, in collaboration with subject matter experts in influenza virology, diagnosis, epidemiology, ecology, and laboratory research in animal and human influenza, developed a framework for assessing the relative risk posed by emerging influenza viruses and an accompanying tool – the Influenza Risk Assessment Tool (IRAT). Those results then inform prioritization of resources for preparedness efforts directed at particular strains/sub-types (e.g., vaccine development).

The IRAT provides a formal method for evaluating the relative risk posed by different emerging influenza strains (e.g., H5N1 versus H7N9).[603,604] This method is based on SME input about risk elements that govern the likelihood that a particular strain will adapt to efficiently transmit in human populations and the expected public health consequences of that emergence event. These risk elements can be broadly grouped into four categories:

- Elements relating to the properties of the virus (e.g., transmissibility and virulence),
- Elements relating to the attributes of host populations (e.g., the degree of pre-existing immunity),
- Elements relating to epidemiological, and
- Elements relating to ecological factors (e.g., the extent of human infections and the prevalence and geographic distribution of the virus in animal populations).

Selected elements will be described in more detail below. Risk elements pertaining to the properties of the virus are informed by virological data (e.g., transmission studies in ferrets) and by genomic data, including molecular marker data (e.g., whether molecular markers associated with enhanced transmissibility in ferrets are present in the viral genetic sequence). Individual risk elements are weighted, based on SME input about their relative contribution to the likelihood and expected consequences of

emergence of particular strains, and all elements are considered collectively to determine an overall risk score. Notably, although not all policy decisions related to pandemic preparedness rely on formal risk assessments, the same factors are considered when informally evaluating the risks posed by emerging influenza viruses.

Potential Benefits of GoF to pandemic risk assessments: utility and limitations of using molecular marker data

GoF approaches have potential to improve the accuracy, timeliness, and quantity of phenotypic information generated by inspecting sequences for the presence of molecular markers for mammalian adaptation, transmissibility, and virulence, as described in detail in Section 9.6.3.2.3. This section focuses on the utility and limitations of molecular marker data to the pandemic risk assessment process.

Molecular marker data

Molecular markers for phenotypes underlying mammalian adaptation, transmissibility, and virulence are considered as part of the "genomic variation" risk element (which also incorporates consideration of reassortment). As described above, these analyses complement results from laboratory-based phenotypic assays. The major strength of this analysis is that sequence data are now the fastest, most reliable data produced at NICs and other field laboratories where animal influenza viruses of concern are circulating, enabling evaluation of viruses prior to the generation of virological data in the laboratory.[605] However, the predictive value of molecular markers is compromised by significant sources of scientific uncertainty, as described above. Because of these uncertainties, molecular marker data contributes moderately to the risk assessment, relative to other factors. For example, in the three-virus relative risk assessment referenced above, findings related to epidemiology risk elements were about six-fold more important than findings in the genomic variation risk element.

9.6.3.3.3 Public Health Impacts of Pandemic Risk Assessments

Pandemic risk assessments are carried out to help prioritize resources for investments in pre-pandemic vaccine development. Risk assessments may also guide investments in other pandemic preparedness initiatives, such as testing the efficacy of antivirals against high-risk viruses. GoF approaches aid decision-making downstream of pandemic risk assessments insofar as GoF-derived data contributes to the pandemic risk assessment process. Additionally, GoF approaches can be used to select particular viruses to be used as the basis of pre-pandemic vaccine strains.

Pre-pandemic vaccine development

Because existing influenza vaccines are strain-specific, pre-pandemic vaccines are developed to target particular groups of high-risk strains. Depending on the overall level of risk associated with a particular virus, the US government will fund development of a pre-pandemic vaccine through various stages of the vaccine production pipeline. Each of the following steps requires an escalating expenditure of resources: CVV development, conduct of pre-clinical vaccine studies in animals, manufacture of clinical trial lots of vaccine, conduct of human clinical trials, stockpiling of vaccine, and priming the population against the novel influenza virus. Collectively, these investments will increase the availability of vaccines during a pandemic by shortening vaccine production timelines.[606] Although the pre-pandemic vaccine strain is unlikely to exactly match the strain that emerges to cause a pandemic, use of adjuvants and prime-boost regimens broaden the protection that can be achieved using a strain-specific vaccine, such that pre-

[605] (2015h) Interview with CDC Representative.
[606] (2015c) Current practices in influenza vaccine production. Interview with Industry or Federal Government Representative with Expertise in Influenza Vaccine Production.

pandemic vaccines are highly likely to provide some level of protection against infection with a similar strain.[607,608] Notably, resources limit the scope of the USG's investment in pre-pandemic vaccines, highlighting the need for strategies to prioritize vaccine development for the many influenza viruses circulating in nature that have spilled over into human populations.

GoF data may play a role in the decision to develop a CVV for an animal influenza virus by contributing to the pandemic risk assessment process, particularly when new viruses first emerge in human populations and sequence data are available before other types of virologic data. Once the decision is made to develop a CVV, multiple strains may be available to serve as the basis for the CVV. In the event that these strains have similar epidemiological and virological characteristics, the presence and type of molecular markers for mammalian adaptation, transmissibility, and virulence can serve to differentiate between strains. This application of GoF data enables more granular decision-making than would have been possible based on other data sources alone, which is valuable because resource limitations constrain that number of CVVs that can be produced.[609]

Both animal influenza viruses isolated from human infections as well as animal influenza viruses that have not yet caused human infections can be subjected to a risk assessment (formally or informally). However, because of the expense involved in each step of pre-pandemic vaccine production, none of the above steps are likely to be undertaken unless multiple human infections have occurred.[610] As a result, although GoF approaches may aid the interpretation of surveillance data from animals, this proximal benefit will not lead to downstream investments in pre-pandemic vaccine development but rather is limited to deepening understanding of the risk associated with particular viruses.

A completely different strategy for increasing the availability of vaccines during a pandemic is by shortening vaccine production timelines. GoF research that enhances virus production enables the development of higher-yield CVVs, which shortens vaccine production timelines by increasing the rate of bulk antigen production. Although this research can be immediately applied to improve vaccine production, this strategy provides the greatest benefit to the production of vaccines using poor-growing CVVs. However, as any strain may unexpectedly generate a low-yield CVV, such as the 2009 H1N1 pandemic strain, this benefit could significantly alleviate morbidity and mortality in the event that future pandemic strains are also grow poorly.

Field investigations of clusters of zoonotic influenza infections abroad

The CDC participates in missions to investigate zoonotic influenza cases or clusters of concern abroad, in conjunction with the WHO, OIE, Food and Agricultural Organization of the United Nations (FAO), and local Ministries of Health. The goal of these missions is to supplement foundational surveillance with in-depth investigations of ecological and environmental factors that may be contributing to spillover, such as sources of human exposure and the extent to which the viruses are circulating in local animal populations.[611] Collectively, these data improve understanding of the risk posed by the zoonotic influenza virus in that environment, which informs decision-making about other prevention and preparedness activities (such as whether to develop a pre-pandemic CVV). Recent examples include missions to Cambodia to investigate an abrupt rise in human H5N1 infections in 2013, to China in 2013 to investigate

the initial wave of H7N9 human infections, and to Cairo, Egypt in March of 2015 to investigate the dramatic increase in the number of human cases of H5N1 infection recorded at the end of 2014 leading into the first few months of 2015.[612,613] The decision to send a CDC team abroad is informed by an assessment of whether the sequences of human isolates contain molecular markers for mammalian adaptation, virulence, and transmissibility. Similar to a formal risk assessment, this decision is driven by epidemiologic data, but the presence of molecular markers of concern adds value by increases certainty in decision-making. In addition, consideration of molecular marker data may stimulate increased attention to investigations of the local animal population and human interactions with infected animals, undertaken to better understand how ecological and environmental factors are influencing the evolution of the virus in that area.

9.6.3.4 Vaccines

GoF approaches have the potential to benefit the development of pre-pandemic vaccines. Specifically, pandemic risk assessments, which can be informed by GoF research (see Section 9.6.3.3), may trigger the development of candidate vaccine viruses based on high-risk viruses, as well as subsequent stages of the pre-pandemic vaccine production pipeline (e.g., manufacturing of clinical lot material, conducting human clinical trials, and stockpiling vaccine).

9.6.3.5 Therapeutics

A lack of knowledge about whether existing therapeutics will be effective against future pandemic strains hampers preparedness planning. GoF-generated viruses that are transmissible between ferrets may mimic pandemic variants of that HA subtype better than wild type viruses. Thus, testing whether existing therapeutics are capable of mitigating disease caused by GoF strains could inform pandemic preparedness planning. Researchers have also suggested that these experiments could stimulate the development of new therapeutics, in the event that existing therapeutics are found to be ineffective against GoF strains. However, the relevance and utility of this information is severely constrained by several sources of uncertainty, including a lack of knowledge about whether ferret-transmissible viruses are more transmissible in humans, whether laboratory-generated transmissible viruses behave similarly to those that could arise in nature, and other factors. Given this uncertainty, dedication of resources to developing therapeutics targeting hypothetical future pandemic viruses is unlikely. Thus, this putative benefit to the development of therapeutics is not considered in this report.

9.6.3.6 Diagnostics

Because the process of developing influenza diagnostics is well-established, GoF research does not inform diagnostic development.[614,615]

9.6.3.7 Economic Benefits

Pandemic risk assessments inform prioritization of resources for pandemic preparedness. Specifically, evaluating the relative risk posed by different influenza viruses helps decision-makers allocate limited funds to pandemic preparedness efforts, such as the development of pre-pandemic vaccines targeting

613 (2015a) Interview with U.S. CDC (Centers for Disease Control) representative.

614 New diagnostics for novel influenza viruses are typically real-time PCR assays which include two or three diagnostic targets. The influenza M gene is used as a marker for influenza A, the HA gene is used for sub-typing, and the NA gene may also be included. Developing of a new diagnostic assay simply requires designing new primers and probes for a virus of interest, which requires that the sequences of the M, HA, and NA genes are available.

615 (2015a) Interview with U.S. CDC (Centers for Disease Control) representative.

high-risk viruses. This prioritization may improve the efficiency of government spending on influenza pandemic preparedness. Economic benefits were not explicitly evaluated in this report.

9.6.4 Identification of the potential benefits and limitations of alt-GoF approaches that provide similar potential benefits to the GoF approaches being examined

In this section, an overview of alternative (alt-GoF) approaches that yield the same or similar benefits as the GoF approaches described above is provided. Two types of alt-GoF approaches are reviewed: (1) alternative experimental approaches that can provide the same or similar scientific information as GoF experimental approaches, and (2) alternative scientific and technical innovations that can yield the same public health benefits as GoF approaches, but through different mechanisms. For each approach, the scientific outcomes of the approach and how that information leads to similar benefits as GoF approaches are described.

9.6.4.1 Potential Benefits and Limitations of Alt-GoF to Scientific Knowledge

9.6.4.1.1 Scientific Knowledge Gap 1: Can Animal Influenza Viruses Become Transmissible Between Humans?

Characterizing the transmissibility of wild type isolates in representative animal models represents an alternative approach for addressing whether animal influenza viruses display the capacity for transmission between mammals. However, this approach is inherently reactive – that is, it can effectively answer whether a virus is transmissible but cannot shed light on whether a virus has the potential to become transmissible. Additionally, observations in animal models may not translate to humans.

9.6.4.1.2 Scientific Knowledge Gap 2: How Do Animal Influenza Viruses Adapt to and Become Transmissible in Humans?

Several alt-GoF approaches can address how influenza viruses evolve to efficiently infect and transmit in humans. First, the comparison of sequences from closely related human and animal isolates enables the identification of the origin and evolutionary rate of genetic changes among circulating viruses, which can provide information on selection pressures and diversity among viruses in different hosts. That this approach examines the natural course of adaptation and underlying mechanisms of infection and transmission of viruses *in humans* is a strength relative to GoF approaches and other alternatives that depend on the suitability of animal models in an artificial environment as representative of human disease. However, this approach suffers from several significant limitations. The use of comparative sequence analysis is feasible only if human-adapted and transmissible viruses have arisen in nature, but to date, animal influenza viruses have limited capacity to infect and transmit in humans. Analysis of the few animal-origin spillover infections may however inform evolution of adaptive traits. The success of this approach is significantly constrained by the quality and availability of genetic surveillance data. In particular, the noisiness of comparative sequence analysis due to high genetic diversity among influenza viruses practically limits this approach to the examination of genetic regions known to be important for adaptation and transmissibility, unless precursor-spillover paired strains can be identified (which is rare). Additionally, the fact that the surveillance record is static and incomplete limits the depth of evolutionary information that can be gleaned from this approach.

Analysis of viruses that have emerged from avian or mammalian reservoirs to become transmissible in other mammalian species represents another surveillance-based approach for studying the mechanisms underlying adaption to mammals during interspecies transmission. The recent emergence of animal transmissible influenza viruses in other mammals (e.g., an avian-origin H3N2 canine influenza virus that emerged in dogs in the mid-2000s) enables the study of the full evolutionary pathway for cross-species

acquisition of efficient transmissibility. This approach is subject to the same limitations as comparative sequence analysis of human and animal isolates, with the additional caveat that adaptation to other mammals may occur through different pathways and mechanisms than in humans.

Phenotypic characterization of wild type viruses by evaluating infectivity and transmissibility in appropriate model systems is another alt-GoF approach for studying the evolution and mechanisms of adaptation/transmissibility. This approach allows the generation of in-depth information about evolutionary mechanisms; however, relevant evolutionary changes may not occur during a single round of transmission. Moreover, any animal influenza viruses that are highly attenuated in representative animal models or are incapable of establishing infection are not suitable for this approach. Finally, this approach depends on the suitability of the animal models used for characterization.

9.6.4.1.3 Scientific Knowledge Gap 3: What Are the Genetic and Phenotypic Traits That Result in Adaption and Transmission in Humans?

Several alt-GoF approaches can be used to uncover genetic and phenotypic traits underlying adaptation and transmission in mammals. First, comparing the sequences of human and animal isolates enables the identification of genetic changes that are associated with human adaptation and transmissibility. This approach has the potential to directly identify human-adaptive traits and may be more likely to uncover conserved traits through analysis of a large number of strains. However, the fact that no animal influenza viruses that efficiently transmit in humans have been observed in nature precludes the use of this approach to identify mechanisms underlying transmissibility. For the discovery of mammalian adaptive traits, the success of this approach is constrained by the quality and availability of surveillance data. In addition, the extensive genetic diversity within circulating virus populations and among viruses isolated from humans makes discerning distinct genetic traits that are likely to contribute to fitness and transmissibility in humans relative to animals difficult. Namely, the "noise" associated with sequences comparisons obscures the discovery of relevant features that distinguish human versus animal isolates, which practically limits this approach to the investigation of traits or regions previously known to be important for adaptation.

Comparing the sequences of evolutionarily related isolates from different animal species represents another surveillance-based approach for identifying genetic traits that are associated with mammalian adaptation and transmissibility. Importantly, because avian-origin flu viruses that are airborne or contact transmissible exist in circulation in several mammals including seals, horses, and dogs, this approach is currently feasible for the study of transmissibility. In addition to the limitations above, mechanistic insight gleaned through this approach may not translate to the adaptation of animal influenza viruses to humans.
